Membrane-Associated Enzymes. At least 50 membrane-bound or membrane-associated enzymes are known to exist in the human erythrocyte. Acetylcholinesterase is an externally oriented enzyme whose role in the function of the erythrocyte remains obscure. Its function is inhibited by certain xenobiotics, most notably the organic phosphorus insecticides, and it can be conveniently assayed as a marker for such exposures ([Chap. 113](#)).

Metabolism. Lacking mitochondria and the ability to generate adenosine triphosphate (ATP) using molecular oxygen, the mature erythrocyte has a severely limited repertoire of intermediary metabolism compared to most mammalian cells. Having lost its nucleus, ribosomes, and translational apparatus, new enzymes cannot be synthesized and existing enzymes decline in function over the lifetime of the cell. Fortunately, the metabolic demands of the erythrocyte are usually modest, but under conditions of stress the capacity can be overwhelmed, especially among senescent cells. The greatest expenditure of energy under physiologic conditions is for the maintenance of transmembrane gradients and for the contraction of cytoskeletal elements. However, oxidant stress can put severe strain on the metabolic reserves of the erythrocyte, and lead ultimately to the premature destruction of the cell, a process termed hemolysis.

Figure 22–2 illustrates the main metabolic pathways and their purpose. Embden-Meyerhof glycolysis is the only source of ATP for the erythrocyte and consumes approximately 90% of the glucose imported by the cell. The reduced nicotinamide adenine dinucleotide (NADH) generated during glycolysis, which would ordinarily be used for oxidative phosphorylation in cells containing mitochondria, is directed toward the reduction of either methemoglobin to hemoglobin by cytochrome b5 reductase, or pyruvate to lactate. Both pyruvate and lactate are exported from the cell. During glycolysis, metabolism can be diverted into the Rapoport-Luebering shunt, generating 2,3-bisphosphoglycerate (2,3-BPG, formerly known as 2,3-diphosphoglycerate or 2,3-DPG) in lieu of ATP. 2,3-BPG binds to deoxyhemoglobin to modulate oxygen affinity and allow unloading of oxygen at the capillaries. In response to anemia, altitude, or changes in cellular pH, the activity of the shunt increases, thereby favoring synthesis of 2,3-BPG and increasing oxygen delivery considerably. Reduced [levels] of 2,3-BPG in stored blood result in impaired oxygen delivery following massive transfusion.⁹⁸

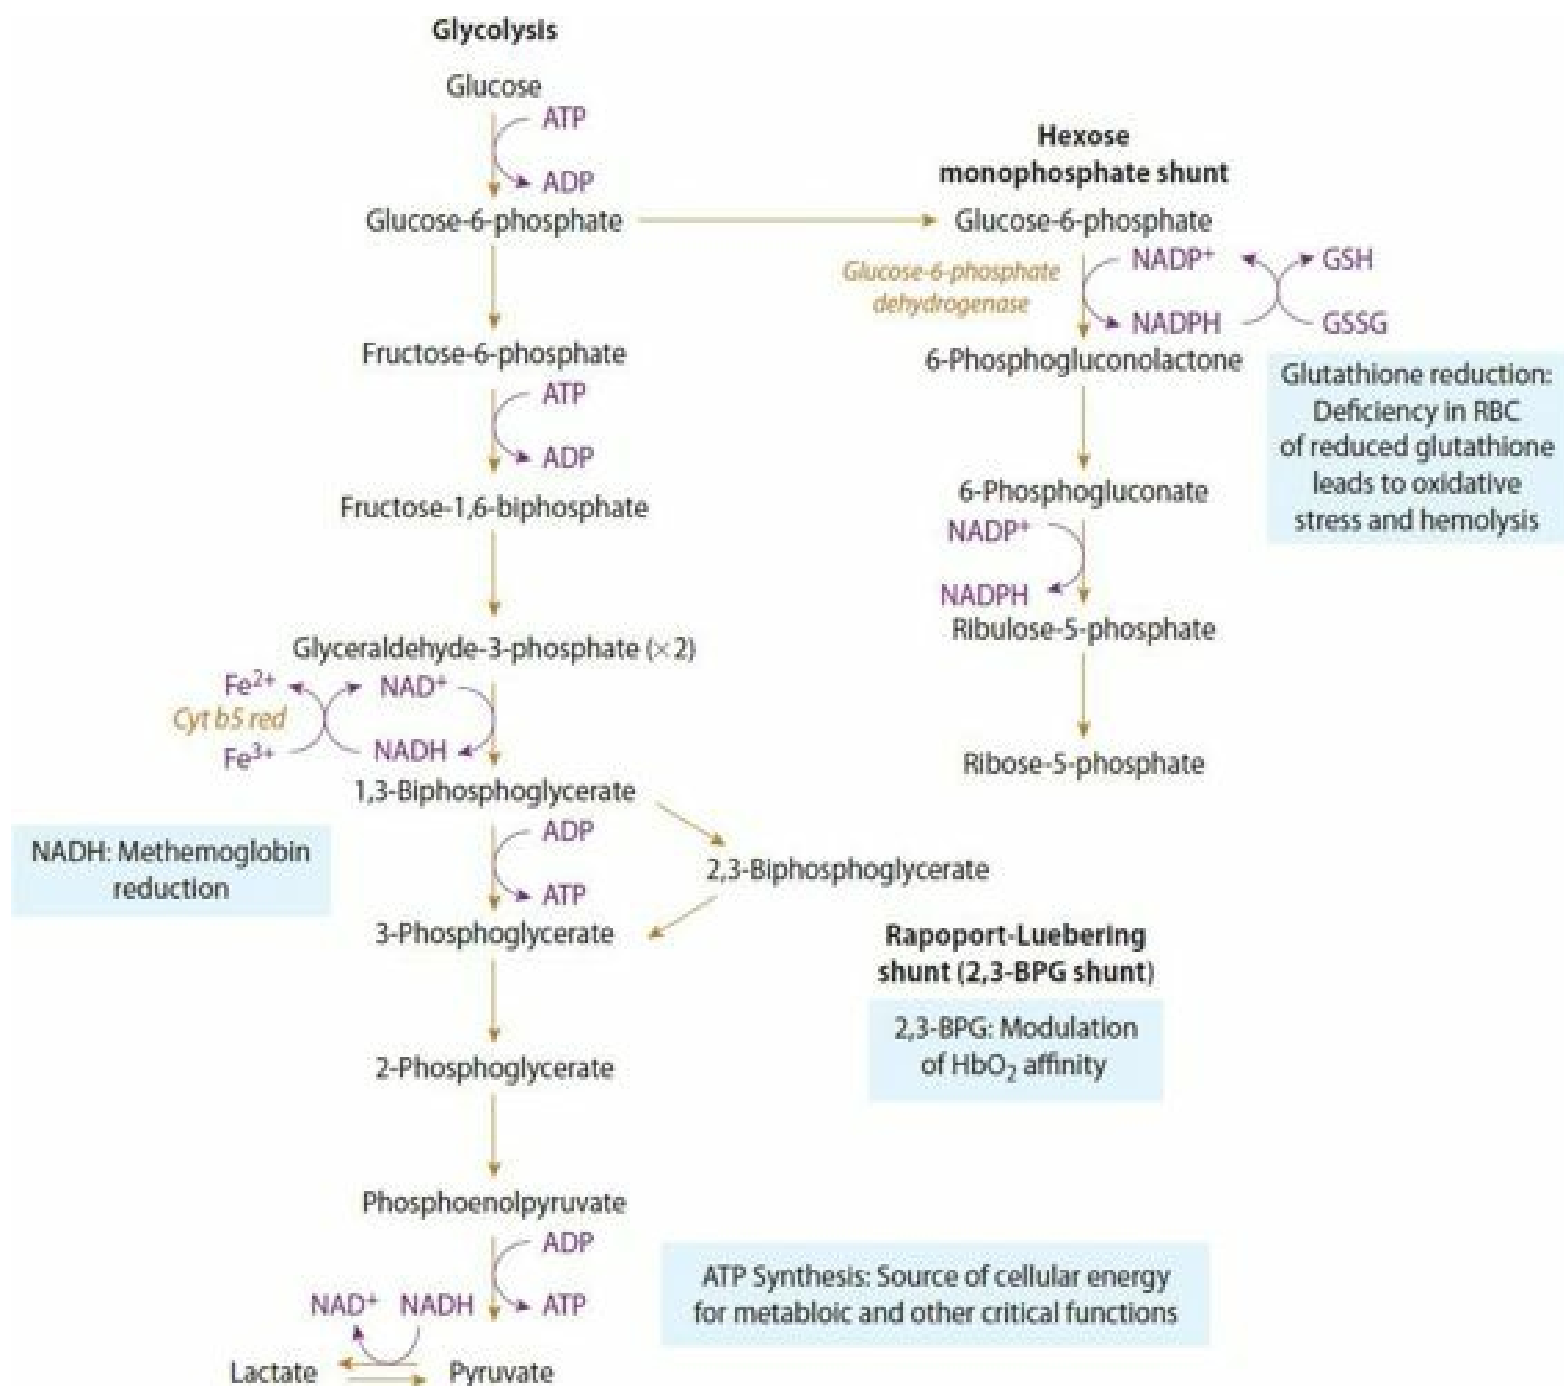

FIGURE 22–2. Metabolic pathways of the erythrocyte. The main metabolic pathways available to the mature erythrocyte are shown (rectangles). Glucose is imported into the cell, while pyruvate, lactate, and oxidized glutathione (GSSG) are exported. 2,3-BPG = 2,3-bisphosphoglycerate; ADP = adenosine diphosphate; ATP = adenosine triphosphate; cyt b5 red = cytochrome b5 reductase; G6PD = glucose-6-phosphate dehydrogenase; GSH = reduced glutathione; Hb = hemoglobin; NADH = reduced form of nicotinamide adenine dinucleotide (NAD⁺); NADPH = reduced form of nicotinamide adenine dinucleotide phosphate (NADP⁺); RBC = red blood cell (erythrocyte).

As an alternative to glycolysis, glucose can be directed toward the hexose monophosphate shunt during times of oxidant stress. This pathway results in the generation of reduced nicotinamide adenine dinucleotide phosphate (NADPH), which the erythrocyte uses to maintain reduced glutathione which, in turn, inactivates oxidants and protects the sulfhydryl groups of hemoglobin and other proteins. The initial, rate-limiting step of this pathway is controlled by glucose-6-phosphate dehydrogenase (G6PD). Accordingly, cells deficient in this enzyme are less able to maintain glutathione in a reduced state, and are vulnerable to irreversible damage under oxidant stress. The consequences of this deficiency are discussed in greater detail below under Glucose-6-Phosphate Dehydrogenase Deficiencies.

The erythrocyte also contains enzymes to synthesize glutathione (γ -glutamyl-cysteine synthetase and glutathione synthetase), to convert CO₂ to bicarbonate ion (carbonic anhydrase I), to remove pyrimidines resulting from the degradation of RNA (pyrimidine 5'-nucleotidase), to protect against free radicals (catalase, superoxide dismutase, glutathione peroxidase), and to conjugate glutathione to electrophiles (ρ -glutathione-S-transferase).

Hemoglobin

Hemoglobin, the major constituent of the cytoplasm of the erythrocyte, is a conjugated protein with a molecular weight of

64,500 Da. To put things in perspective, the typical adult man has approximately 75 mL/kg of blood containing 15 g/100 mL of hemoglobin, or nearly 1 kg of hemoglobin. His 0.3-kg heart must pump this entire mass of hemoglobin every minute at rest, which is a substantial work expenditure. One molecule is composed of four protein (globin) chains, each attached to a prosthetic group called heme. Heme contains an iron molecule complexed at the center of a porphyrin ring. The globin chains are held together by noncovalent electrostatic attraction into a tetrahedral array. Hemoglobin is so efficient at binding and carrying oxygen that it enables blood to transport 100 times as much oxygen as could be carried by plasma alone (Chap. 29). In addition, the capacity of hemoglobin to modulate oxygen binding under different conditions allows adaptation to a wide variety of environments and demands. Three complex and integrated pathways are required for the formation of hemoglobin: globin synthesis, protoporphyrin synthesis, and iron metabolism.

Globin Synthesis. The protein chains of hemoglobin are produced with information from two different genetic loci. The α -globin gene cluster spans 30 kb on the short arm of chromosome 16, and codes for two identical adult α -chain genes, as well as the ζ -chain, an embryonic globulin. The β cluster is 50 kb on chromosome 11, and codes for the two adult globins β and α , as well as two nearly identical γ chains expressed in the fetus and an embryonic globulin ϵ . The expression of genes in each family changes during embryonic, fetal, neonatal, and adult development. Until 8 weeks of intrauterine life, ϵ , ζ , γ , and α chains are produced and assembled in various combinations in yolk sac–derived erythrocytes. With the shift in erythropoiesis from yolk sac to fetal liver and spleen, embryonic hemoglobin disappears, and the α and γ globin chains are paired into fetal hemoglobin (HbF = $\alpha_2\gamma_2$). Erythrocytes containing HbF have a higher O_2 affinity than those containing adult hemoglobin, which is important for oxygen transfer across the placenta into the relatively hypoxic uterine environment. Beginning shortly before birth, expression shifts to the α and β globins, which constitute the predominant adult hemoglobin termed hemoglobin A ($\alpha_2\beta_2$). Approximately 2.5% of normal adult hemoglobin is in the form of hemoglobin A₂ ($\alpha_2\delta_2$). The thalassemias, a group of inherited disorders, result from defective synthesis of one or more of the globin chains. Clinically this results in a hypochromic, microcytic anemia.

Heme Synthesis. Heme is the iron complex of protoporphyrin IX. Protoporphyrin IX is a tetramer composed of four porphyrin rings joined in a closed, flat-ring structure. The IX designation refers to the order in which it was first synthesized in Hans Fischer's laboratory. Of the 15 possible isomers, only protoporphyrin IX occurs in living organisms. Technically, only iron complexes with the iron in the Fe^{2+} state can be called heme, but the term is commonly used to refer to the prosthetic group of metalloproteins such as peroxidase (ferric) and cytochrome c (both ferric and ferrous), whether the iron is in the Fe^{2+} or Fe^{3+} state. The terms “hemoglobin” and “ferrihemoglobin” are synonymous with methemoglobin but rarely used. All animal cells can synthesize heme, with the notable exception of mature erythrocytes. Hemoproteins are involved in a multitude of biologic functions, including oxygen binding (hemoglobin, myoglobin), oxygen metabolism (oxidases, peroxidases, catalases, and hydroxylases), and electron transport (cytochromes), as well as metabolism of xenobiotics (cytochrome P450 family). Erythroid cells synthesize 85% of total body heme, with the liver synthesizing most of the balance. Hemoglobin is the most abundant hemoprotein, containing 70% of total body iron.

The first step in the synthesis of heme takes place in the mitochondrion and is the condensation of glycine and succinyl-coenzyme A (CoA) to form 5-aminolevulinic acid (ALA) (Fig. 22–3). The formation of 5-ALA is catalyzed by aminolevulinic acid synthase (ALAS), the rate-limiting step of the pathway. The rate of heme synthesis is closely controlled, given that free intracellular heme is toxic and that this first step is essentially irreversible.

FIGURE 22–3. The heme synthesis pathway. The enzymatic steps inhibited by lead are marked in red. 5-ALA = 5-aminolevulinic acid; RBCs = red blood cells.

Of the two isoforms of ALAS known to exist in mammals, erythroid cells express the ALAS2 isoform, which resides on the X chromosome. Comparatively more is known about ALAS1 (chromosome 3), a housekeeping gene with a short half-

life expressed ubiquitously, allowing the synthesis of cellular and mitochondrial hemoproteins. ALAS1 activity is induced by many factors, which can increase its expression by two orders of magnitude. Moreover, it is strongly inhibited by heme in a classical negative feedback fashion. ALAS2 is constitutively expressed at very high concentrations in erythroid precursors, allowing sustained synthesis of heme during erythropoiesis. Pyridoxal phosphate (active vitamin B₆) serves as a cofactor to both isoforms of ALAS. The clinical consequences of pyridoxine deficiency include a hypochromic, microcytic anemia, iron overload, and neurologic impairment.

The next step in the synthesis of hemoglobin is the formation of the monopyrrole porphobilinogen via the condensation of two molecules of ALA. The subsequent steps in heme synthesis involve the condensation of four molecules of porphobilinogen into a flat ring, which is transported back into the mitochondrion by an unknown mechanism. The final step is the insertion of iron into protoporphyrin IX, a reaction that is catalyzed by ferrochelatase (also known as heme synthase) to form heme.

Understanding this carefully regulated synthetic pathway is relevant to understanding the laboratory evidence of lead toxicity ([Chap. 96](#)), and predicting the response of porphyric patients to a range of xenobiotics. Most steps in the heme biosynthetic pathway are inhibited by lead. ALA dehydratase is the most sensitive, followed by ferrochelatase, coproporphyrinogen oxidase, and porphobilinogen deaminase. As a consequence, ALA is increased in plasma and especially urine. With increasing exposure, ferrochelatase inhibition coupled with iron deficiency causes zinc protoporphyrin to accumulate in erythrocytes, which can easily be detected by fluorescence. Coproporphyrinogen III also appears in the urine. Historically, these effects have served as the basis for a number of tests of lead exposure.

The porphyrias are a group of disorders resulting from an inherited deficiency of any given enzyme that follows ALAS on the heme biosynthetic pathway. As such, when ALAS activity outpaces the activity of the deficient enzyme, the rate-limiting step shifts downstream, and intermediate metabolites accumulate. These metabolites can cause characteristic neuropsychiatric symptoms and palsies (caused by ALA and porphobilinogen), and cutaneous reactions, including photosensitivity (due to the fluorescence of the porphyrins). For example, porphobilinogen is excreted in large quantities by patients with acute intermittent porphyria (porphobilinogen deaminase deficiency), and the urine darkens with exposure to air and light due to oxidation to porphobilin and to nonenzymatic assembly into porphyrin rings. A variety of xenobiotics can precipitate a crisis in susceptible individuals, by inducing ALAS1 and overloading the deficient enzyme.⁹⁷ The molecular mechanisms that allow xenobiotics to induce the ALAS1 gene closely resemble those accounting for induction of the cytochrome P450 (CYP) genes, which also require heme synthesis. The xenobiotic typically interacts with either the constitutive androstane receptor (CAR) or the pregnane X receptor (PXR), the two main so-called orphan nuclear receptors.¹⁰⁴ These transcriptional factors are DNA-binding proteins that induce the expression of a range of drug metabolizing and transporting genes in response to the presence of a xenobiotic and are termed “xenosensors.” When activated, they associate with the 9-cis retinoic acid xenobiotic receptor (RXR), and then attach to enhancer sequences near the apoCYP or ALAS1 genes to enhance transcription.⁷⁸ The multifunctional inducers capable of activating a wide range of hepatic enzymes are therefore extremely porphyrogenic and include phenobarbital, phenytoin, carbamazepine, and primidone. Furthermore, because CYP 3A4 and 2C9 represent nearly half of the hepatic CYP pool, inducers of these isoforms also stimulate heme synthesis and can induce a porphyric crisis. Examples include the anticonvulsants; nifedipine; sulfamethoxazole; rifampicin; ketoconazole; and the reproductive steroids progesterone, medroxyprogesterone, and testosterone. Glucocorticoids, on the other hand, despite binding to PXR, suppress ALAS1 induction and translation, and they are not porphyrogenic.⁹⁷

Iron Metabolism. At equilibrium, approximately 1 to 2 mg of iron is absorbed from the diet, and a similar amount is shed from the intestinal epithelium each day. Unless appropriately chelated, free iron not bound by transport or storage proteins can generate harmful oxygen free radicals that damage cellular structures and metabolism ([Chaps. 12 and 46](#)). For this reason, serum iron circulates bound to a transfer protein, transferrin, and is stored in the tissues using ferritin ([Fig. 22–4](#)). Whereas each molecule of transferrin can bind two iron atoms, ferritin has a large internal cavity, approximately 80 Å in diameter, that can hold up to 4500 iron atoms per molecule. The amount of iron transported through plasma depends on total-body iron stores and the rate of erythropoiesis. Only about one-third of the iron-binding sites of circulating transferrin are normally saturated, as demonstrated by the usual serum iron content of 60 to 170 µg/dL (10–30 µmol/L) as compared to the total iron-binding capacity of 280 to 390 µg/dL (50–70 µmol/L).

FIGURE 22–4. The iron cycle. The flow of iron is indicated by arrows, and average daily rates of flux are shown for an adult. Absorption at the duodenal enterocyte is tightly controlled, because there are few physiologic processes to regulate losses (other than pregnancy and menstruation). Atomic iron is absorbed via the divalent metal transporter 1, and heme-bound iron via heme carrier protein 1. Hepcidin is an important circulating peptide inhibitor of ferroportin, thereby limiting absorption when stores are adequate. Iron content (either atomic or heme-bound) of specific organs or compartments is shown in milligrams. The largest stores of atomic iron are contained by ferritin, mostly in liver and spleen macrophages, and erythrocyte precursors in the marrow. Only a relatively small amount circulates in the plasma bound to transferrin, which is usually only partially saturated. EPO = erythropoietin; RBC = red blood cell.

Only transferrin can directly supply iron for hemoglobin synthesis. The iron–transferrin complex binds to transferrin receptors on the surface of developing erythroid cells in bone marrow. Iron in the erythroid cell is used for hemoglobin synthesis or is stored in ferritin.

The absorption of nonheme, free ferrous iron from the diet occurs via the divalent metal transporter one of the duodenal enterocyte, which then passes it into the circulation via ferroportin. Iron then circulates in the ferric form bound to transferrin.⁴⁵ Dietary iron complexed with heme can be absorbed via the recently discovered heme carrier protein 1, which transports either iron or zinc protoporphyrin into the enterocyte.⁹¹ The iron may then be freed by microsomal heme oxygenase and follow the transport of atomic iron, or perhaps heme itself can be transferred to the circulation via specific export proteins and circulate bound to its carrier protein, hemopexin.⁵

When the erythrocyte is removed from the circulation by splenic macrophages, heme is degraded by heme oxygenase to

carbon monoxide and biliverdin, and the iron extracted. Some iron may remain in macrophages in the form of ferritin or hemosiderin. Most is delivered again by ferroportin back to the plasma and bound to transferrin.

Iron homeostasis is largely regulated at the level of absorption, with little physiologic control over its rate of loss. Excess absorption relative to body stores is the hallmark of hereditary hemochromatosis. The iron regulatory hormone hepcidin produced by the liver is now believed to play a central role in iron control, including the anemia of chronic disease caused by inflammatory signals.⁴⁵ Hepcidin is a 25-amino acid peptide that senses iron stores and controls the ferroportin-mediated release of iron from enterocytes, macrophages, and hepatocytes. The liver is an important reservoir of iron because it can store considerable amounts of iron taken from portal blood and release it when needed.

Oxygen-Carbon Dioxide Exchange

The evolutionary transition of organisms from anaerobic to aerobic life allowed the liberation of 18 times more energy from glucose. Vertebrates have developed two important systems to overcome the relatively small quantities of oxygen dissolved in aqueous solutions under atmospheric conditions: the circulatory system and hemoglobin. The circulatory system allows delivery of oxygen and removal of carbon dioxide throughout the organism. Hemoglobin plays an essential role in the transport and exchange of both gases. Moreover, the interactions between these gases and hemoglobin are directly linked in a remarkable story of molecular evolution. Understanding this interplay has allowed fundamental insight into protein conformation and the importance of allosteric interactions between molecules.

The binding of one oxygen molecule to each of the four iron atoms in heme results in conformational changes that affect binding of oxygen at the remaining sites. This phenomenon is known as cooperativity, and it is necessary to both the transport of relatively large quantities of oxygen and the unloading of most of this oxygen at tissue sites. Cooperativity results from the intramolecular interactions of the tetrameric hemoglobin, and is expressed in the sigmoidal shape of the oxyhemoglobin dissociation curve (Fig. 29–2). Conversely, the monomeric myoglobin has a hyperbolic oxygen binding curve. The partial pressure of oxygen at which 50% of the oxygen bindings sites of hemoglobin are occupied is about 26 mm Hg, in contrast with about 1 mm Hg for myoglobin. Moreover, hemoglobin is nearly 100% saturated at partial oxygen pressures of about 100 mm Hg in the pulmonary capillaries, transporting 1.34 mL of oxygen per gram of hemoglobin A. About one-third of this oxygen can be unloaded under normal conditions at tissue capillaries with partial oxygen pressures around 35 mm Hg. The proportion unloaded rises during exercise and sepsis, as well as with xenobiotics that uncouple oxidative phosphorylation. Elite athletes can extract up to 80% of the available oxygen under conditions of maximal aerobic effort.

The oxygen reserve, however, is only one of the benefits of the large quantity of hemoglobin in circulation. The ability of hemoglobin to buffer the acid equivalent of CO₂ in solution is equally vital to respiratory physiology, because it allows the removal of large quantities of CO₂ from metabolically active tissues with minimal changes in blood pH. Hemoglobin is by far the largest buffer in circulation, accounting for seven times the buffer capacity of the serum proteins combined (28 vs. 4 mEq H⁺/L of whole blood). For every 1 mole of oxygen unloaded in the tissue, about 0.5 mole of H⁺ is loaded onto hemoglobin.

The linked interaction between oxygen and carbon dioxide transport can be first considered from the perspective of oxygen binding to hemoglobin. The affinity of oxygen for hemoglobin is directly affected by pH, which is a function of the CO₂ content of the blood. The oxyhemoglobin dissociation curve shifts to the left in lungs, where the level of carbon dioxide, and thus carbonic acid, are kept relatively low as a result of ventilation, an effect that promotes oxygen binding. The curve shifts to the right in tissues where cellular respiration increases CO₂ concentrations. This phenomenon, known as the Bohr effect, promotes the uptake of oxygen in the lungs and the release of oxygen at tissue sites.

From the perspective of carbon dioxide transport, hemoglobin also plays an essential albeit indirect role. Carbon dioxide dissolves into plasma, and is slowly hydrated to carbonic acid which dissociates to H⁺ and HCO₃⁻ (pK_a 6.35). The speed of the hydration reaction is accelerated from about 40 seconds to 10 msec by the abundant enzyme carbonic anhydrase located within the erythrocyte. Most carbon dioxide collected at the tissues diffuses into erythrocytes, where it becomes H⁺ and HCO₃⁻. This HCO₃⁻ is then rapidly transported back to the serum in exchange for chloride ion via the band 3 anion exchange transporter located in the erythrocyte membrane, thereby shifting serum Cl⁻ into the erythrocyte (the chloride shift). The hydrogen ion is accepted by hemoglobin, largely at the imidazole ring of histidine residues, which have a pK_a of about 7.0. A small amount of CO₂ reacts directly with the amino terminal of the globin chains to form carbamino residues (HbNHCOO⁻). Thus, most of the transported carbon dioxide is transformed by the erythrocyte into bicarbonate ion that is returned to the serum and hydrogen ion that is buffered by hemoglobin. Each liter of venous blood typically carries 0.8 mEq dissolved CO₂ + 16 mEq HCO₃⁻ in the plasma, 0.4 mEq dissolved CO₂ + 4.6 mEq HCO₃⁻, + 1.2 mEq HbNHCOO⁻ in the erythrocyte (a total of 23 mEq CO₂, equivalent to 510 mL CO₂/L blood). Although two-thirds of the total CO₂ content is ultimately carried in the plasma, nearly all of the bicarbonate is generated within erythrocytes. In the capillaries of the lungs, the reverse reactions occur to eliminate CO₂. Because deoxyhemoglobin is better able to buffer

hydrogen ions, the release of oxygen from hemoglobin at the tissues facilitates the uptake of carbon dioxide into venous blood. This effect is known as the Haldane effect. In fact, 1 L of venous blood at 70% oxygen saturation can transport an additional 20 mL of CO₂ compared to arterial blood, which is nearly 100% saturated. Both the Bohr and Haldane effects can have important consequences at the extremes of acid–base perturbations, as can occur in a number of poisonings that interfere with oxygen metabolism.

Finally, in addition to inactivating nitric oxide, hemoglobin can also reversibly bind it as S-nitrosohemoglobin, thereby playing an important role in the regulation of microvascular circulation and oxygen delivery. The ability of hemoglobin to vasodilate the surrounding microvasculature in response to oxygen desaturation using nitric oxide provides new insight into oxygen delivery and may be pivotal in such disorders as septic shock, pulmonary hypertension, and senescence of stored red blood cells.⁹²

Abnormal Hemoglobins

Several alterations of the hemoglobin molecule are encountered in clinical toxicology. A detailed understanding of their molecular basis, clinical manifestations, and effects on gas exchange is essential. Unfortunately, the nomenclature can be ambiguous and overlaps with distinct clinical entities such as oxidant injury and hemolysis. Therefore, although a detailed discussion of these abnormal hemoglobins appears elsewhere ([Chaps. 125 and 127](#)), an overview of the subject is presented here. It is helpful to recall that the iron atom has six binding positions. Four of these positions are attached in a single plane to the protoporphyrin ring to form heme. The remaining two binding positions lie on opposite sides of this plane. One site is ordinarily bonded to the F8 proximal histidine residue of the globin chain. The remaining site is available for binding molecular oxygen, but it can also bind carbon monoxide, nitric oxide, cyanide, hydroxide ion, or water. The E7 distal histidine residue facilitates the binding of oxygen while sterically hindering carbon monoxide binding.

Methemoglobin. Methemoglobin (ferrihemoglobin or hemoglobin) is the oxidized form of deoxyhemoglobin in which at least one heme iron is in the oxidized (Fe³⁺) valence state. A number of valency hybrids can occur, depending on the number of ferric versus ferrous heme units within the tetramer. Methemoglobin therefore represents oxidation (loss of electrons) of the hemoglobin molecule at the iron atom. It occurs spontaneously as a consequence of interactions between the iron and oxygen. Normally, in deoxygenated hemoglobin, the heme iron is in the ferrous (Fe²⁺) valence state. In this state, there are six electrons in the outer shell, four of which are unpaired. When oxygen is bound, one of these electrons is partially transferred to it and the iron is reversibly oxidized. When O₂ is released, the electron is usually transferred back to heme iron, yielding the normal reduced state. Sometimes, the electron remains with the O₂ yielding a superoxide anion radical O₂[−] rather than molecular oxygen. In this case, heme iron is left in the Fe³⁺, or oxidized, state and is unable to release another electron to bind oxygen. This oxidation is primarily reversed via the action of cytochrome b5 reductase, also known as NADH methemoglobin reductase, which uses the electron carrier NADH generated by glycolysis (Metabolism discussion above and [Chap. 13](#)). Minor pathways are also involved in methemoglobin reduction, including NADPH methemoglobin reductase, which normally reduces only approximately 5% of the methemoglobin, and vitamin C, a nonenzymatic reducing agent. The activity of NADPH methemoglobin reductase may be significantly accelerated by the presence of the electron donor methylene blue (*Antidotes in Depth: A42* and [Chap. 127](#)) or riboflavin. Equilibrium is maintained with methemoglobin concentrations of 1% of total hemoglobin. Many xenobiotics increase the rate of methemoglobin formation by as much as 1000-fold. Nitrites, nitrates, chlorates, and quinones are capable of directly oxidizing hemoglobin.¹⁹ Certain individuals may be especially vulnerable resulting from deficient methemoglobin reduction.²⁸ The fetus and neonate are more susceptible to methemoglobinemia than the adult, because HbF is more susceptible to oxidation of the heme iron than adult hemoglobin. The newborn also has a limited capacity to reduce methemoglobin, because adult concentrations of cytochrome b5 reductase are only achieved at about 6 months of age.

Carboxyhemoglobin. Carbon monoxide (CO) can reversibly bind to heme iron in lieu of molecular oxygen. The affinity of CO for hemoglobin is 200–300 times that of oxygen, despite the steric hindrance of the E7 distal histidine. The presence of CO thereby precludes the binding of oxygen. In addition, CO binding within any one heme subunit degrades the cooperative binding of oxygen at the remaining heme groups of the same hemoglobin molecule. The oxyhemoglobin dissociation curve is therefore shifted to the left, reflecting the fact that oxygen is more tightly bound by hemoglobin and less able to be unloaded to the tissues. In addition, CO binds to the heme group of myoglobin and the cytochromes, interfering with cellular respiration and exacerbating the hypoxia ([Chap. 125](#)).⁴¹

Sulfhemoglobin. Sulfhemoglobin is a bright green molecule in which the hydrosulfide anion HS[−] irreversibly binds to ferrous hemoglobin. The sulfur atom is probably attached to a β carbon in the porphyrin ring and not at the normal oxygen-binding site.⁶⁷ It has a spectrophotometric absorption band at approximately 618 nm,¹⁶ is ineffective in oxygen transport, and clinically produces a condition that resembles cyanosis. The oxygen affinity of sulfhemoglobin is approximately 100 times less than that of oxyhemoglobin, shifting the oxyhemoglobin dissociation curve to the right, in favor of O₂ unbinding. Thus, the symptoms of hypoxia are not as severe with sulfhemoglobinemia as with carboxy- or methemoglobinemia.⁷⁴

Oxidation of the Globin Chain. Oxidation can also occur at the amino acid side chains of the globin protein. In

particular, sulfhydryl groups can oxidize to form disulfide links between cysteine residues, which leads to the unfolding of the protein chain, exposure of other side chains, and further oxidation. When these disulfide links join adjacent hemoglobin molecules, they cause the precipitation of the concentrated hemoglobin molecules out of solution. Covalent links can also form between hemoglobin and other cytoskeletal and membrane proteins.²⁵ Eventually, aggregates of denatured and insoluble protein are visible on light microscopy as Heinz bodies. The distortion of the cellular architecture and the loss of fluidity in particular signal reticuloendothelial macrophages to excise sections of erythrocyte membrane (“bite cells”) or to remove the entire erythrocyte from the circulation (see below). To guard against these oxidation reactions, the erythrocyte maintains a pool of reduced glutathione via the actions of the NADPH generated in the hexose monophosphate shunt (assuming adequate G6PD activity to initiate this pathway). This glutathione transfers electrons to break open disulfide links and to preserve sulfhydryl groups in their reduced state.

Hemolysis

Hemolysis is merely the acceleration of the normal process by which senescent or compromised erythrocytes are removed from the circulation.⁹³ The normal life span of a circulating erythrocyte is approximately 120 days, and any reduction in this life span represents some degree of hemolysis. If sufficiently rapid, hemolysis can overwhelm the regenerative capacity of the erythron, resulting in anemia. Intravascular hemolysis occurs when the rate of hemolysis exceeds the capacity of the reticuloendothelial macrophages to remove damaged erythrocytes, and free hemoglobin and other intracellular contents of the erythrocyte appear in the circulation.

Reticulocytosis, polychromasia, unconjugated hyperbilirubinemia, increased serum lactate dehydrogenase, and decreased serum haptoglobin are characteristic of hemolysis. A normal or elevated RBC distribution width and thrombocytosis are usually present. The presence of spherocytes on peripheral blood smear suggests an autoimmune or hereditary process and can be pursued with a Coombs’ test. Schistocytes suggest thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome, disseminated intravascular coagulation, or valvular hemolysis. TTP and hemolytic uremic syndrome are characterized by a microangiopathic anemia, thrombocytopenia, and normal coagulation parameters (unlike disseminated intravascular coagulation). TTP is discussed under platelet disorders below. Hemoglobinemia, hemoglobinuria, and hemosiderinuria can occur with intravascular hemolysis. Specialized tests to measure hemolysis detect shortened erythrocyte survival, increased endogenous carbon monoxide generation from heme oxygenase, and increased fecal urobilinogen.

Table 22–2 presents a brief classification of acquired causes of hemolysis relevant to toxicology. Oxidant injury following xenobiotic exposure is one of the triggers of hemolysis, as it may cause irreversible changes in the erythrocyte. Erythrocytes deficient in G6PD by virtue of cell age or enzyme mutations are particularly vulnerable to hemolysis following oxidant stress due to limited capacity to generate NADPH and reduced glutathione.⁹³ The immune-mediated hemolytic anemias occur when ingested xenobiotics trigger an antigen antibody reaction. In general, these molecules are too small to be sensitizing agents, but antigenicity can be acquired after binding to carrier proteins in blood. The particulars of the xenobiotic-carrier immune activation sequence form the basis for the classification of this group of hemolytic anemias.⁷

TABLE 22–2. Xenobiotics Causing Acquired Hemolysis

Immune-mediated

Type I: IgG against drug tightly bound to red cell

High-dose penicillin

Type II: Complement activated by antibodies against drug-membrane complex

Cefotaxime, cefotetan, ceftriaxone, quinidine, stibophen

Type III: True autoimmune response to red cell membrane

Chlorpromazine, cladribine, cyclosporine, fludarabine, levodopa, methyldopa, procainamide

Nonimmune-mediated

Oxidants

Aniline

Benzocaine

Chlorates
Dapsone
Hydrogen peroxide
Hydroxylamine
Methylene blue
Naphthalene
Nitrites
Nitrofurantoin
Oxygen
Phenacetin
Phenazopyridine
Phenol
Platinoids
Sulfonamides
Nonoxidants
Arsine (AsH_3)
Copper
Lead
Pyrogalllic acid
Stibine (SbH_3)
Hypophosphatemia
Microangiopathic (eg, ticlopidine, clopidogrel, cyclosporine, tacrolimus)
Osmotic agents (eg, water)
Venoms (snake, spider)

Nonimmune-Mediated Causes of Xenobiotic-Induced Hemolysis

A number of xenobiotics or their reactive metabolites can cause hemolysis via oxidant injury. A Heinz-body hemolytic anemia can result, which typically resolves within a few weeks of drug discontinuation. Some xenobiotics cause hemolysis in the absence of overt oxidant injury ([Table 22–2](#)). Copper sulfate hemolysis is described in [Chap. 95](#), while the delayed hemolysis following exposure to arsine or stibine is described here.

Arsine (AsH_3) is a colorless, odorless, nonirritating gas that is 2.5 times denser than air ([Chap. 89](#)). Clinical signs and symptoms appear after a latent period of up to 24 hours after exposure to concentrations above 30 ppm and may include headache, malaise, dyspnea, abdominal pain with nausea and vomiting, hepatomegaly, hemolysis with hemoglobinuric acute kidney injury, and death.^{23,34,53,57,77} The mechanism of hemolysis is believed to involve the fixation of arsine by sulfhydryl groups of hemoglobin and other essential proteins.^{39,103} Interestingly, hemolysis is prevented in vitro by conversion to carboxy- or methemoglobin.⁴⁴ Impairment of membrane proteins, including $\text{Na}^+\text{-K}^+\text{-ATPase}$, is another potential mechanism for arsine-induced hemolysis.⁸⁰ Chronic exposure to low levels of arsine can produce clinically significant disease.²³ Stibine (SbH_3), an antimony derivative, likely causes hemolysis via similar mechanisms ([Chap. 88](#)).

Glucose-6-Phosphate Dehydrogenase Deficiencies. G6PD is the enzyme that catalyzes the first step of the hexose monophosphate shunt: the conversion of glucose-6-phosphate to phosphogluconolactone (Fig. 13–7). In the process, NADP⁺ is reduced to NADPH, which the erythrocyte uses to maintain a supply of reduced glutathione and to defend against oxidation. It follows that erythrocytes deficient in G6PD activity are less able to resist oxidant attack and, in particular, to maintain sulfhydryl groups of hemoglobin in their reduced state, resulting in hemolysis. It is important to recognize that the term G6PD deficiency encompasses a wide range of differences in enzyme activities among individuals. These differences may result from decreased enzyme synthesis, altered catalytic activity, or reduced stability of the enzyme. Approximately 7.5% of the world population is affected to some degree, with more than 400 variants having been identified. Most cases involve relatively mild deficiency and minimal morbidity. Ethnic populations from tropical and subtropical countries (the so-called malaria belt) have a much higher prevalence of G6PD deficiency, possibly because that phenotype protects against malaria.⁶⁹

The gene that encodes for G6PD resides near the end of the long arm of the X-chromosome. Most mutations consist of a single amino acid substitution, as complete absence of this enzyme is lethal. Although men hemizygous for a deficient gene are more severely affected, women randomly inactivate one X-chromosome during cellular differentiation according to the Lyon hypothesis. Thus, women carriers heterozygous for a deficient G6PD gene have a mosaic of erythrocytes, some proportion of which expresses the deficient gene during maturation. Accordingly, approximately 10% of carrier women may be nearly as severely affected as males hemizygous for the same deficient gene. Because of the high gene frequency in certain ethnic groups, another approximately 10% of women may be homozygous for the deficient gene.

Normal G6PD has a half-life of about 60 days. Because the erythrocyte cannot synthesize new protein, the activity of G6PD normally declines by approximately 75% over its 120-day life span. Consequently, even in unaffected individuals, susceptibility to oxidant stress varies based on the age mix of circulating erythrocytes. In all cases, older erythrocytes are less likely to recover following exposure to an oxidant and will hemolyze first. Moreover, after an episode of hemolysis following acute exposure to an oxidant stress, the higher G6PD activity of surviving erythrocytes will confer some resistance against further hemolysis in most individuals with relatively mild deficiency, even if the offending xenobiotic is continued. For this reason, phenotypic testing for G6PD deficiency is best done 2 to 3 months after a hemolytic crisis, which is when the reticulocyte count has usually normalized.

The World Health Organization classification of G6PD is based on the degree of enzyme deficiency and severity of hemolysis.¹⁸ Both class I and class II patients are severely deficient, with less than 10% of normal G6PD activity. Class I individuals are prone to chronic hemolytic anemia, whereas class II patients experience intermittent hemolytic crises. Class III patients have only moderate (10%–60%) enzyme deficiency, and experience self-limiting hemolysis in response to certain xenobiotics and infections. Approximately 11% of African Americans have a class III deficiency, traditionally termed type A[−], and experience a decline of no more than 30% of the red blood cell mass during any single hemolytic episode. Another 20% of African Americans have type A⁺ G6PD enzyme, which is functionally normal, and therefore of no consequence despite a one-base substitution compared to wild-type B. The Mediterranean type found in Sardinia, Corsica, Greece, the Middle East, and India is a class II deficiency, and hemolysis can occur spontaneously or in response to ingestion of oxidants, such as the β-glycosides found in fava (*Vicia fava*) beans.

The most common clinical presentation of previously unrecognized G6PD deficiency is the acute hemolytic crisis. Typically, hemolysis begins 1 to 4 days following the exposure to an offending xenobiotic or infection (Table 22–3). Jaundice, pallor, and dark urine may occur with abdominal and back pain. A decrease in the concentration of hemoglobin occurs. The peripheral smear demonstrates cell fragments and cells that have had Heinz bodies excised. Bone marrow stimulation results in a reticulocytosis by day 5 and an increased erythrocyte mass. In general, a normal bone marrow can compensate for ongoing hemolysis and can return the hemoglobin concentration to normal. Most crises are self-limiting because of the higher G6PD activity of younger erythrocytes. Historically, the anemia observed when primaquine was administered to type A[−] military recruits for malaria prophylaxis resolved within 3 to 6 weeks in most cases.¹⁷ Some xenobiotics, including APAP, vitamin C, and sulfisoxazole, are safe at therapeutic doses but can cause hemolysis in G6PD-deficient patients following overdose.

Doxorubicin

Furazolidone

Isobutyl nitrite

Methylene blue

Nalidixic acid

Naphthalene
Nitrofurantoin
Phenazopyridine
Phenylhydrazine
Primaquine
Sulfacetamide
Sulfamethoxazole
Sulfanilamide
Sulfapyridine
Toluidine blue
Trinitrotoluene

Data adapted from Beutler E: Glucose-6-phosphate dehydrogenase deficiency. *N Engl J Med.* 1991;324: 169–174, and Beutler E: G6PD deficiency. *Blood.* 1994;84:3613–3636.

Other presentations of more severe variants of G6PD include neonatal jaundice and kernicterus, chronic hemolysis with splenomegaly and black pigment gallstones, megaloblastic crisis caused by folate deficiency, and aplastic crisis after parvovirus B19 infection.

Megaloblastic Anemia

Vitamin B₁₂ and folate are essential for one-carbon metabolism in mammals. One-carbon fragments are necessary for the biosynthesis of thymidine, purines, serotonin, and methionine; the methylation of DNA, histones, and other proteins; and the complete catabolism of branched chain fatty acids and histidine. Unable to synthesize vitamin B₁₂ or folate, mammals are dependent on dietary sources and microorganisms for these cofactors. The hematologic manifestation of vitamin B₁₂ or folate deficiency is a characteristic pancytopenia termed megaloblastic anemia. The hallmark nuclear-cytoplasmic asynchrony is due to disrupted DNA synthesis, halted interphase and ineffective erythropoiesis.⁷⁹ The hyperplastic bone marrow contains precursor cells with abnormal nuclei filled with incompletely condensed chromatin. Among circulating blood cells, macrocytic anemia (macro-ovalocytes) without reticulocytosis is followed by the appearance of granulocytes with an abnormally large, distorted nucleus (hypersegmented neutrophils with six or more lobes). Lymphocytes and platelets may appear normal but are also functionally impaired.

In addition to dietary deficiencies, which have become less common, macrocytic anemia with or without megaloblastosis in adults is usually caused by chronic ethanol abuse, chemotherapeutics, or antiretrovirals, especially when mean corpuscular volumes are only moderately elevated (100–120 fL).⁸⁷ The folate antagonists aminopterin, methotrexate, hydantoins, pyrimethamine, proguanil, sulfasalazine, trimethoprim sulfamethoxazole, and valproate can interfere with DNA synthesis. Ethanol affects folate metabolism and transport. Vitamin B₁₂ deficiency can be induced by chronic exposure to nitrous oxide, biguanides, colchicine, neomycin, and the proton pump inhibitors. Purine analogs (eg, azathioprine, 6-mercaptopurine, 6-thioguanine, acyclovir) and pyrimidine analogs (eg, 5-fluorouracil, floxuridine, 5-azacitidine, and zidovudine) also disrupt nucleic acid synthesis. Hydroxyurea and cytarabine, which inhibit ribonucleotide reductase, also delay nuclear maturation and function and frequently cause megaloblastosis.

Pure Red Cell Aplasia

Pure red cell aplasia is an uncommon condition in which erythrocyte precursors are absent from an otherwise normal bone marrow. It results in a normocytic anemia with inappropriately low reticulocyte count. The other blood cell lines are unaffected, unlike aplastic anemia. Pharmaceuticals cause fewer than 5% of cases of this uncommon condition, having been implicated in fewer than 100 human reports.⁹⁶ Only phenytoin, azathioprine, and isoniazid meet criteria for definite causality; chlorpropamide and valproic acid can be considered only as possible causes.⁹⁶ Most other xenobiotics are cited only in single case reports, and drug rechallenge was not used, making the association uncertain.

In part because of its rarity, a cluster of 13 cases in France of pure red cell aplasia in hemodialysis patients receiving subcutaneous recombinant EPO ultimately led to an international effort by researchers, regulatory authorities, and industry

to identify the etiology.^{14,26} To reduce theoretical concerns regarding transmission of variant Creutzfeldt-Jakob disease, human serum albumin was replaced with polysorbate 80 as the stabilizer in a formulation used in Europe and Canada. It is suspected that this change allowed rubber to leach from the uncoated stopper of prefilled syringes, triggering an immune response against both recombinant and endogenous EPO in some patients.⁶³ This episode not only serves as a recent example of successful pharmacovigilance for rare adverse drug effects but has also influenced safety assessments for an emerging class of biological therapies that include simple peptides, monoclonal antibodies, and recombinant DNA proteins.^{13,63}

Erythrocytosis

Erythrocytosis denotes an increase in the red cell mass, either in absolute terms or relative to a reduced plasma volume. An increasingly recognized cause of drug-induced absolute erythrocytosis is the abuse of recombinant human EPO by athletes to enhance aerobic capacity (Chap. 40). Autologous blood transfusions (doping) are also used in this population, and both can cause dangerous increases in blood viscosity. Cobalt was once considered for the treatment of chronic anemia³² due to its ability to cause a secondary erythrocytosis (Chap. 94). The mechanism may involve impaired degradation of the transcription factor hypoxia-inducible factor 1 α , thereby prolonging EPO transcription. This effect is more pronounced in high altitude dwellers, in whom elevated serum EPO concentrations persist despite hematocrits in excess of 75% and chronic mountain sickness is associated with increased serum cobalt concentrations.⁵²

THE LEUKON

The leukon represents all leukocytes (white blood cells), including precursor cells, cells in the circulation, and the large number of extravascular cells. It includes the granulocytes (neutrophils, eosinophils, and basophils), lymphocytes, and monocytes. Neutrophils (polymorphonuclear leukocytes) are highly specialized mediators of the inflammatory response, and are a primary focus of concern regarding hematologic toxicity of xenobiotics. B and T lymphocytes are involved in antibody production and cell-mediated immunity. Monocytes migrate out of the vascular compartment to become tissue macrophages and to regulate immune system function.

Immunity is generally divided into the innate and the adaptive responses. Innate immunity is an immediate but less specific defense that is highly conserved in evolutionary terms. It is centered on the neutrophil response, and it involves monocytes and macrophages as well as complement, cytokines, and acute phase proteins. The innate system responds primarily to extracellular pathogens, especially bacteria, by recognizing structures commonly found on pathogens, namely lipopolysaccharide (Gram-negative cell walls), lipoteichoic acid (Gram positive), and mannans (yeast). Adaptive immunity is demonstrated only in higher animals and is an antigen-specific response via T- and B-lymphocytes after antigen presentation and recognition. Although this reaction is more specific, it requires several days to develop, unless that antigen has previously triggered a response (so-called immune memory). This response can also at times be directed against self-antigens, resulting in autoimmune disorders.

The recruitment and activation of neutrophils provide the primary defense against the invasion of bacterial and fungal pathogens. They emerge from the bone marrow with the biochemical and metabolic machinery needed for the efficient killing of microorganisms. Activated macrophages release G-CSF and GM-CSF, which stimulate myeloid differentiation and can be recognized on blood testing as the classic neutrophil leukocytosis. Neutrophils are activated when circulating cells detect chemokines released from sites of inflammation. On activation, they undergo conformational and biochemical changes that transform them into powerful host defenders. These changes allow rolling along the endothelial lining of postcapillary venules, migration toward the site of inflammation, adherence to the endothelium, migration through the endothelium to tissue sites, ingestion, killing, and digestion of invading organisms.

Neutrophils migrate to sites of infection along gradients of chemoattractant mediators. An acute inflammatory stimulus leads to the accumulation of neutrophils along the endothelium of postcapillary venules. The major molecules involved in this process are adhesion molecules, chemoattractants, and chemokines. Loose adhesions between neutrophils and endothelium are made and broken, resulting in the slow movement of leukocytes along endothelium and a more intense exposure of neutrophils to activating factors. Chemotaxis requires responses involving actin polymerization–depolymerization adhesion events mediated by integrins and involving microfilament–membrane interactions. All leukocytes including lymphocytes localize infection using these same mediators. Colchicine depolymerizes microfilaments, causing the dissolution of the fibrillar microtubules in granulocytes and other motile cells, impairing this response.

Opsonized particles, immune complexes, and chemotactic factors activate neutrophils in tissues by binding to cell surface receptors. The neutrophil makes tight contact with its target, and the plasma membrane surrounds the organism completely enclosing it. Two mechanisms are then responsible for the destruction of the organism: the oxygen-dependent respiratory burst, and the oxygen-independent response involving cationic enzymes found in cytoplasmic granules. The respiratory burst is caused by an NADPH oxidase complex that assembles at the phagosomal membrane. Electrons are transferred from cytoplasmic NADPH to oxygen on the phagosomal side of the membrane, generating superoxide, hydrogen peroxide, hydroxyl radical, singlet oxygen, hypochlorous acid, chloramines, nitric oxide, and peroxynitrite. Cytoplasmic

granules within the neutrophil fuse with the phagosome and empty their contents into it. The components of these granules include myeloperoxidase (MPO), elastase, lipases, metalloproteinases, and a pool of CD11b/CD18 proteins required for adhesion and migration. Finally, the phagocytized organism is digested and eliminated by the neutrophil. Overstimulation of this complex and highly regulated but somewhat nonspecific system can at times become deleterious, as is postulated to occur with reperfusion injury or carbon monoxide poisoning, to cite two examples.⁹⁵ Vasculitis and the systemic inflammatory response syndrome are further examples of excessive activation of the innate response.

Neutropenia and Agranulocytosis

Neutropenia is a reduction in circulating neutrophils at least 2 standard deviations below the norm, but the threshold of $1500/\text{mm}^3$ ($1.5 \times 10^9/\text{L}$) is often used instead.⁴⁷ Severe neutropenia is termed agranulocytosis and is generally defined to be an absolute neutrophil count of less than $500/\text{mm}^3$ ($0.5 \times 10^9/\text{L}$). Neutropenia can result from decreased production, increased destruction, or retention of neutrophils in the various storage pools. Their high rate of turnover renders neutrophils vulnerable to any xenobiotic that inhibits cellular reproduction. As such, the various antineoplastics including antimetabolites, alkylating agents, and antimitotics will predictably cause neutropenia. This predictable, dose-dependent reaction represents an important dose-limiting adverse effect of therapy. On the other hand, a number of xenobiotics are implicated in idiosyncratic neutropenia.^{3,4} The parent drug or a metabolite usually acts as a hapten to trigger antineutrophil antibodies. Table 22–4 provides an abbreviated list.^{76,94} Cocaine users are at very high risk for agranulocytosis because of the common contamination of this drug with levamisole (Chap. 78).²²

Eosinophilia

Eosinophils are primarily responsible for protecting against parasitic infection. Allergic reactions and malignancies such as lymphoma are also common causes of eosinophilia, especially where nematode infection is rare.⁸⁵ Eosinophils bind to antigen-specific IgE and discharge their large granules, which contain major basic protein, peroxidase, and eosinophil-derived neurotoxin, onto the surface of the antibody-coated organism. Two unusual toxicologic outbreaks were characterized by eosinophilia, acute cough, fever, and pulmonary infiltrates, followed by severe myalgia, neuropathy, and

eosinophilia. The first outbreak, called the toxic oil syndrome, took place in central Spain in 1981, when industrial-use rapeseed oil denatured with 2% aniline was fraudulently sold as olive oil by door-to-door salesmen.³⁶ The precise causative agent remains uncertain but may include fatty acid esters of 3-(N-phenylamino)-1,2-propanediol.³⁶ The second outbreak, called the eosinophilia-myalgia syndrome, occurred during 1988 and 1989 in users of L-tryptophan supplements traced back to a single wholesaler in Japan.⁶ The causative contaminant has not been identified but is believed to have been present in only trace quantities in the L-tryptophan purified from microbial culture. Both syndromes appear to be mediated by immunologic mechanisms.

Leukemia

The leukemias represent the malignant, unregulated proliferation of hematopoietic cells. Although monoclonal in origin, they affect all cell lines derived from the progenitor cell. Acute myeloid leukemia (AML) and the myelodysplastic syndromes are the most common leukemias associated with xenobiotics. The long-recognized association between AML and occupational benzene exposure, radiation, or treatment with alkylating antineoplastics has helped to advance understanding of the molecular mechanisms underlying leukemogenesis.¹⁵ The necessary events are believed to involve several sequential genetic and epigenetic alterations, as evidenced by a distinct pattern of chromosomal deletions preceding the development of AML.^{49,50} Other recognized xenobiotics that can cause leukemia include topoisomerase II inhibitors, 1,3-butanediol, styrol, ethylene oxide, and vinyl chloride.^{54,75} In many cases, the latency period between exposure and illness is prolonged. For example, leukemia linked to benzene is preceded by several months of anemia, neutropenia, and thrombocytopenia.

HEMOSTASIS

In the absence of pathology, blood remains in a fluid form with cells in suspension. Injury triggers coagulation and thrombosis. The resulting clot formation, retraction, and dissolution involve an interaction between the vessel endothelium, soluble constituents of the coagulation system, and proteins located on and within platelets. Platelets respond to signals within their immediate environment and from injured components of the distant microcirculation. A dynamic balance must be maintained between coagulation and fibrinolysis to maintain the integrity of the circulatory system (Fig. 22–5).

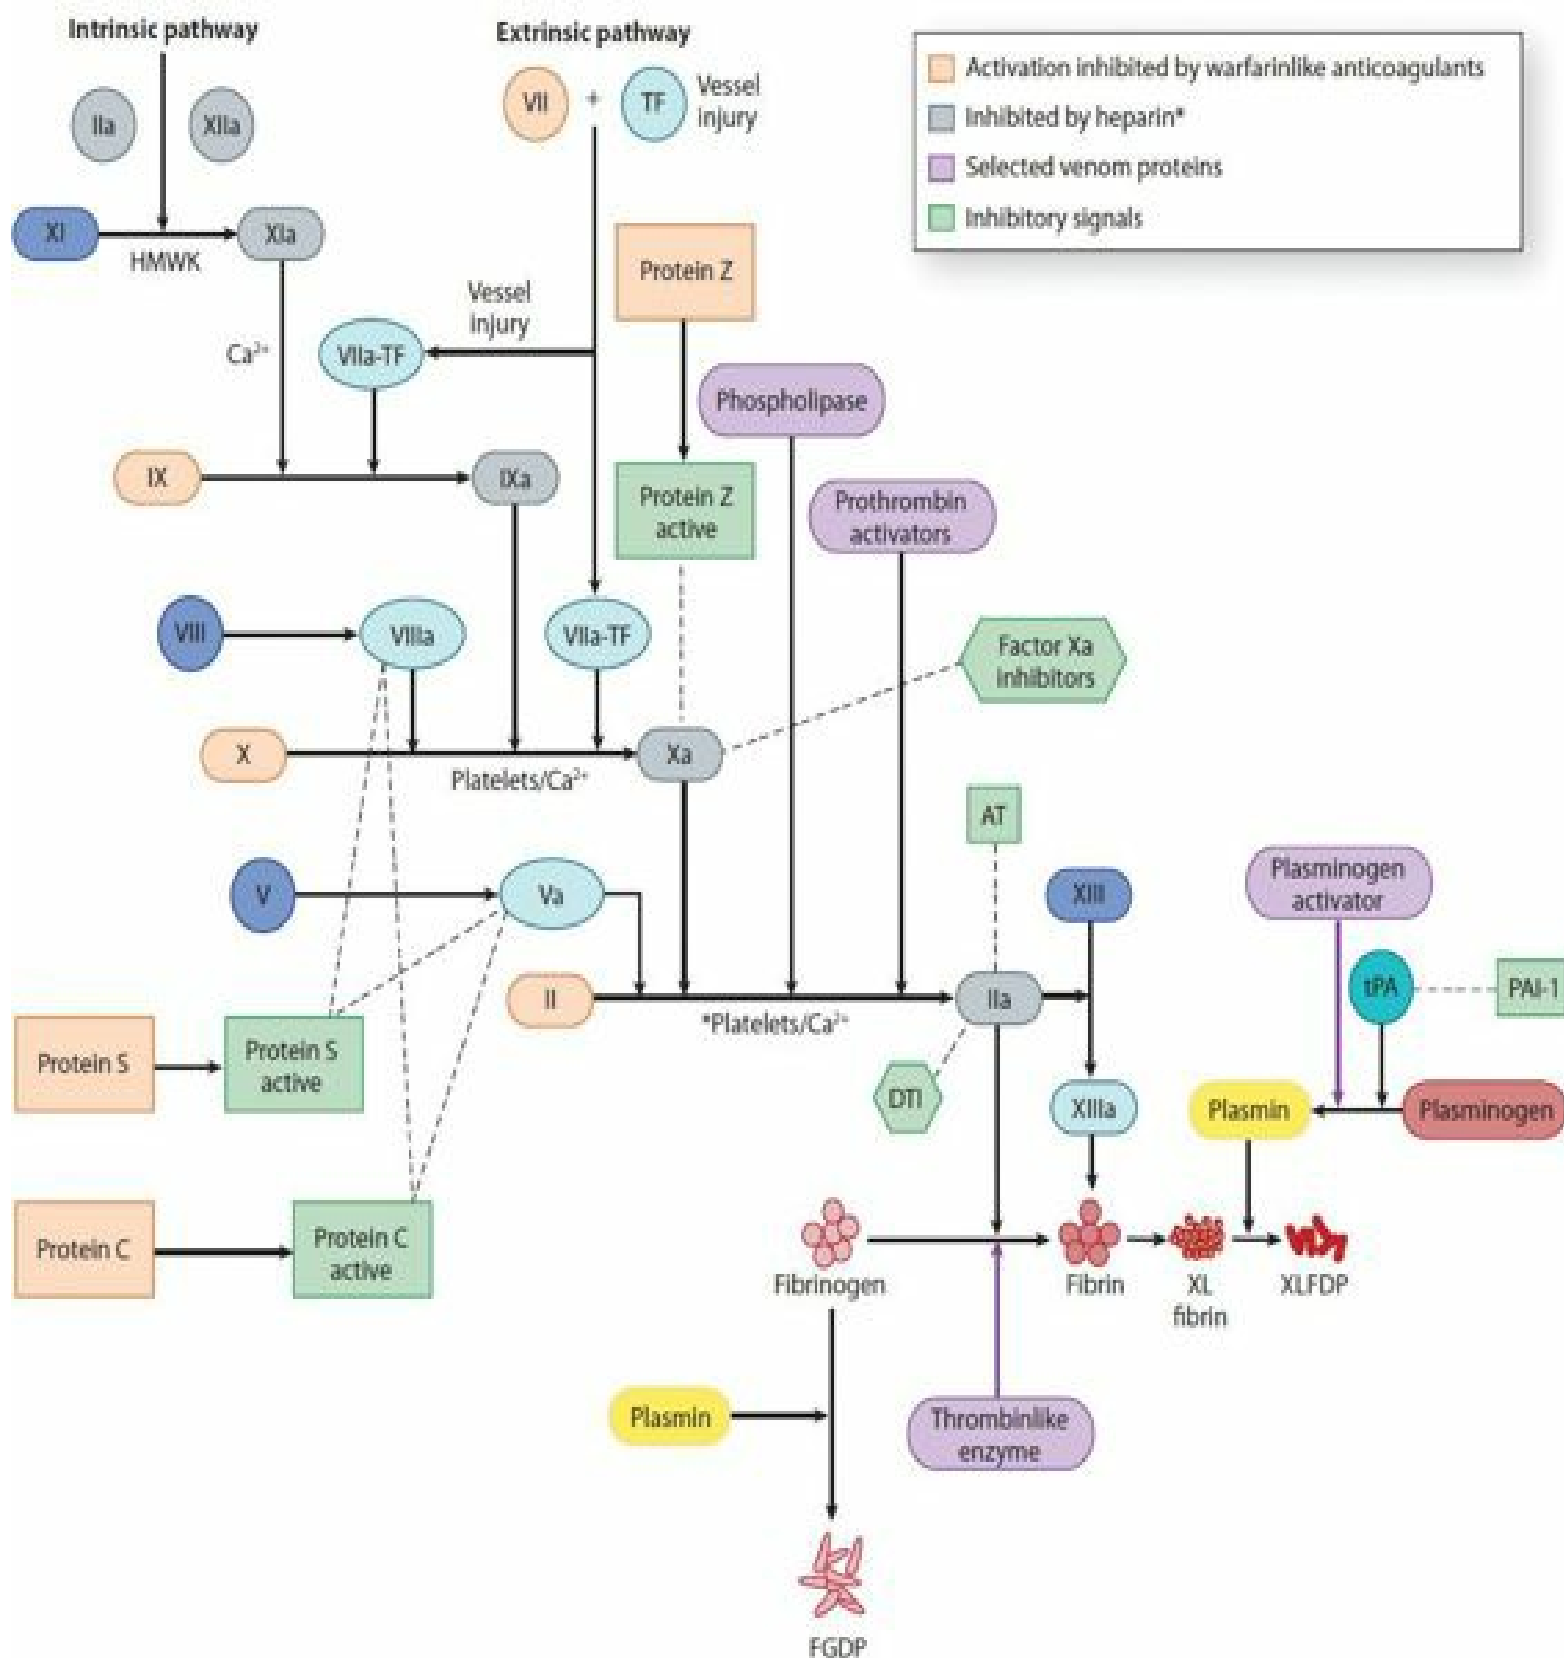

FIGURE 22–5. A schematic overview of the coagulation cascade and fibrinolytic pathway. Selected sites of interaction between phospholipids on the platelet surface and coagulation pathway intermediates are shown, with the exception of tissue factor/VIIa and IXa to VIIIa (to avoid confusion). Similarly, not all sites of interaction between various serine protease inhibitors are shown. Selected venom proteins are indicated by purple boxes. Dashed lines indicate inhibitory effects. FDP = fibrin degradation products; FGDP = fibrinogen degradation products; HMWK = high-molecular-weight kininogen; TF = tissue factor; tPA = tissue plasminogen activator; PAI = plasminogen activator inhibitor; XL = cross-linked.

Coagulation

Two basic pathways termed intrinsic and extrinsic are involved in the initiation of coagulation. The more important extrinsic, or tissue factor, pathway is activated when blood is exposed to tissue factor (also known as thromboplastin) which is normally expressed on subendothelial cells and fibroblasts not in direct contact with blood. Tissue factor activates factor VII and together form the extrinsic tenase complex activating both factors X and IX. The intrinsic, or

contact activation, pathway also activates factor IX, which forms the intrinsic tenase complex with factor VIIIa. Both extrinsic and intrinsic tenase (ie, “ten” –ase) with calcium activate factor X, which binds to factor Va on the surface of activated platelets, forming the prothrombinase complex. The prothrombinase complex activates prothrombin, which results in the generation of thrombin activity. Thrombin activates platelets, promotes its own generation by activation of factors V, VIII, and XI, and converts fibrinogen to fibrin (Chap. 60).⁴⁶

Laboratory Tests of Coagulation

An understanding of several widely available coagulation tests is important to the correct interpretation of the effects of xenobiotics on hemostasis, whether for therapeutic drug monitoring or following overdose. Four studies—prothrombin time (PT, or international normalized ratio {INR}), partial thromboplastin time (PTT), thrombin time, and fibrinogen concentration—are particularly important in the classification of coagulation disorders.

PT assesses the extrinsic coagulation pathway and is calculated by adding standardized thromboplastin reagent (phospholipid and tissue factor) to a sample of the patient’s citrated plasma (the citrate removes calcium to prevent clotting). Calcium is then introduced, and the time to clotting measured. With the exception of factor X, the PT is unaffected by the presence or absence of factors VIII to XIII, platelets, prekallikrein, and high-molecular-weight kininogen (HMWK). An individual’s PT was formerly expressed as a ratio (PT observed to PT control). Because this ratio is directly affected by both laboratory methodology and the source of the thromboplastin reagent used, the generated results suffered from significant variability between laboratories and countries. Thus, the INR was developed in an attempt to limit this variability. The INR is calculated by raising the PT ratio to an exponent known as the International Sensitivity Index (ISI): (PT ratio)^{ISI}. The ISI is calibrated against an international standard to measure responsiveness of the particular thromboplastin to the effects of warfarin.

Although the use of the INR does not completely eliminate variability,^{94,95} it improves warfarin dosing and comparison with international norms. It should be noted that the ISI, and thus the INR, is designed for greater consistency in measuring coagulation changes due to warfarin, and it may in fact be more variable than the PT ratio for patients with other coagulation defects. Specifically, replacing the PT with the INR for prognosis in the setting of fulminant hepatic failure, as may occur following APAP overdose, is controversial.^{24,84} In these patients, the INR may be more variable between laboratories, and the calculation of a substantially different ISI may be warranted.¹¹

The PTT tests both the intrinsic and common coagulation pathway. It is measured by adding calcium and an activator (kaolin, silica, or celite) to citrated plasma and the time to clotting observed. Some tests also use phospholipids in the reagent to activate the remaining coagulation factors, thereby giving rise to the term activated partial thromboplastin time (aPTT). Because the PTT and aPTT are essentially interchangeable, the term PTT is used hereafter to represent the concept. The PTT is not affected by alterations in factors VII, XIII, or platelets.

The thrombin time (or thrombin clotting time), determined by adding exogenous thrombin to citrated plasma, evaluates the ability to convert fibrinogen to fibrin, is thus unaffected by abnormalities of factors II, V, VII to XIII, platelets, prekallikrein, or HMWK. Finally, either a fibrinogen concentration or a determination of fibrin degradation products will help distinguish between problems with clot formation and consumptive coagulopathy (disseminated intravascular coagulation). An evaluation of the combination of normal and abnormal results of these tests usually determines a patient’s clotting abnormality (Table 22–5).

TABLE 22–5. Evaluation of Abnormal Coagulation Times

PT prolonged, PTT normal

Deficiency of factor VII

Warfarin therapy (early)

Vitamin K deficiency (mild)

Liver disease (mild)

PT normal, PTT prolonged, bleeding

Deficiencies of factors VIII, IX, XI

von Willebrand disease

PT normal, PTT prolonged, no bleeding

Deficiencies of factor XII, prekallikrein

High-molecular-weight kininogen inhibitor syndrome

PT and PTT prolonged, thrombin time normal, fibrinogen normal

Deficiencies of factors II, V, IX; vitamin K deficiency (severe) Warfarin therapy (late)

Factor Xa inhibitor therapy (eg, rivaroxaban, apixaban)^{a,b}

PT and PTT prolonged, thrombin time abnormal, fibrinogen normal

Heparin therapy^a

Direct thrombin inhibitor therapy (eg, dabigatran)^c

Dysfibrinogenemia

PT and PTT prolonged, thrombin time abnormal, fibrinogen abnormal

Liver disease

Disseminated intravascular coagulation

Fibrinolytic therapy

Crotaline envenomation

^aPTT insensitive to low-molecular weight heparin effects and less sensitive than PT to factor Xa inhibitor therapy. ^bNormal PT does not exclude effect. ^cProlongation of PTT is not linearly correlated with dabigatran concentration.

PT = prothrombin time; PTT = partial thromboplastin time.

Inhibitors can be diagnosed by “mixing studies,” because only a small percentage of the coagulation factors present in normal plasma are necessary to have normal clotting studies. Factor activity in blood can be as little as 25% of normal without affecting the PT or PTT. Thus, the presence of an abnormal PT or PTT that will not correct despite the addition of an equal volume of normal plasma demonstrates the presence of an inhibitor of coagulation as opposed to a factor deficiency. Heparin-induced anticoagulation results in an elevated PTT that does not correct when mixing studies are performed. More sophisticated studies can be used to identify specific coagulation factor deficiencies.

Xenobiotic-Induced Defects in Coagulation

A rapidly increasing number of xenobiotics are in therapeutic use to antagonize coagulation ([Chap. 60](#)). The recognition of a hemorrhagic disease in cattle in the 1920s and the isolation of the causative agent dicoumarol from spoiled sweet clover in the 1940s resulted in the development of the warfarin-type anticoagulants. This group of anticoagulants indirectly inhibits hepatic synthesis of coagulation factors II, VII, IX, X, and proteins C, S, and Z by inhibiting the reductase that is responsible for the regeneration of vitamin K quinone from vitamin K epoxide. Because warfarin is widely prescribed and has a narrow therapeutic index, efforts to improve our understanding of the pharmacology of warfarin are advancing the fields of pharmacogenomics and drug interactions.¹⁰²

Heparin is a highly sulfated glycosaminoglycan that is normally present in tissues. Commercial unfractionated heparin is either bovine or porcine in origin and consists of a mixture of polysaccharides with molecular weights ranging from 4000 to 30,000 Da. The anticoagulant activity of heparin is through its catalytic activation of antithrombin III, a suicide inhibitor of the serine proteases thrombin and factors IXa, Xa, XIa, and XIIa.⁶⁸

The low-molecular-weight heparins (LMWHs) have a mean molecular weight of 4000 to 6000 Da.⁴⁶ Their subcutaneous bioavailability, more predictable pharmacokinetics, lower protein binding, and longer half-life make them more convenient than unfractionated heparin.⁶⁸

Heparinoids are glycosaminoglycans not derived from heparin with anticoagulant effects. This class includes dermatan sulfate and danaparoid sodium. Fondaparinux is a synthetic pentasaccharide that also inhibits factor Xa by binding to antithrombin III and therefore acts upstream of thrombin. Recently, other oral factor Xa inhibitors have been approved for human use, including rivaroxaban and apixaban. Several direct thrombin inhibitors are also in clinical use, including parenterally administered lepirudin, argatroban, bivalirudin, desirudin, and more recently oral dabigatran. These agents can

prolong the INR, aPTT, thrombin clotting time, and whole-blood activated clotting time.

Fibrinolysis

The coagulation system is opposed by three major inhibitory systems. Components of the fibrinolytic system circulate as zymogens, activators, inhibitors, and cofactors.³³ Plasminogen can be activated to plasmin by an intrinsic pathway involving factor XII, prekallikrein, and HMWK. This produces the degradation products and fibrin monomers that are found in disseminated intravascular coagulation. The extrinsic pathway involves the release of tissue plasminogen activator (t-PA) from tissues and urokinase plasminogen activator (u-PA) from secretions.³³ Once activated, plasmin can degrade fibrinogen, fibrin, and coagulation factors V and VIII. The degradation of cross-linked fibrin strands results in the formation of D-dimers.

Several inhibitors oppose the fibrinolytic system, including α_2 -antiplasmin, α_2 -macroglobulin, both of which oppose plasmin activity, and plasminogen activator inhibitor (PAI) types 1 and 2, which oppose t-PA. PAI-1 and PAI-2 are opposed by activated protein C and protein S. Activated protein C is activated by thrombin. Another vitamin K–dependent glycoprotein, protein Z, accelerates the degradation of factor Xa. Congenital deficiencies of proteins C, S, and Z may result in pathologic venous thrombosis. Decreased fibrinolytic activity may result from decreased synthesis, release of t-PA, or from an elevation of the PAI-1 concentration. Both conditions have been observed postoperatively, with the use of oral contraceptives, in the third trimester of pregnancy, and in obesity. The activity of α_2 -antiplasmin and α_2 -macroglobulin are increased in pulmonary fibrosis, malignancy, infection, and myocardial infarction, and in thromboembolic disease.³³

Xenobiotic-Induced Defects in Fibrinolysis

Table 22–6 lists xenobiotics associated with an acquired defect of fibrinolysis. The chemotherapeutics may result in a reduction in serine protease inhibitors such as antithrombin. L-Asparaginase is associated with a reduction in circulating t-PA concentrations. Methotrexate can damage vascular endothelium, which may trigger thrombosis (Chap. 51).³³ Hemostatic drugs used therapeutically include the synthetic lysine derivatives aminocaproic acid and tranexamic acid, which bind reversibly to plasminogen; the bovine protease inhibitor aprotinin, which inhibits kallikrein; the vasopressin analog desmopressin, which increases plasma concentrations of factor VIII and vWF; and conjugated estrogens, which normalize bleeding times in uremia.⁶²

Platelets

In the resting state, platelets maintain a discoid shape. The platelet membrane is a typical trilaminar membrane with glycoproteins, glycolipids, and cholesterol embedded in a phospholipid bilayer. The plasma membrane is in direct continuity with a series of channels, the surface-connected canalicular system (SCCS), which is sometimes referred to as the open canalicular system. The SCCS provides a route of entry and exit for various molecules, a storage pool for platelet glycoproteins, and an internal reservoir of membrane that may be recruited to increase platelet surface area. This facilitates platelet spreading and pseudopod formation during the process of cell adhesion.

The glycocalyx, or outer coat, is heavily invested with glycoproteins that serve as receptors for a wide variety of stimuli. The β_1 -integrin family includes receptors that mediate interactions between cells and mediators in the extracellular matrix, including collagen, laminin, and fibronectin. The β_2 -integrin receptors are present in inflammatory cells and platelets and are important in immune activation. The β_3 -integrin receptors (also known as cytoadhesins) include the glycoprotein (GP) IIb-IIIa fibrinogen receptor, as well as vitronectin.⁴⁶ Vitronectin has binding sites for other integrins, collagen, heparin, and components of complement. All of the integrins are active in the process of platelet adhesion to surfaces. Platelet aggregation is mediated by the GP IIb-IIIa receptors.⁴⁶

The submembrane region contains actin filaments that stabilize the platelets' discoid shape and are involved in the formation and stabilization of pseudopods. They also generate the force needed for the movement of receptor-ligand complexes from the outer plasma membrane to the SCCS. These mobile receptors are important in the spreading of platelets on surfaces, and for binding fibrin strands and other platelets. Platelet cytoplasm contains three types of membrane bound secretory granules.⁴⁶ The α granules contain β -thromboglobulin, which mediates inflammation, binds and inactivates heparin, and blocks the endothelial release of prostacyclin. In addition, platelet factor-4, which inactivates heparin, and fibrinogen are contained within the α granules. Dense granules store adenine nucleotides, serotonin, and calcium, which are secreted during the release reaction. Platelet lysosomes contain hydrolytic enzymes. Stimulation by platelet agonists causes the granules to fuse with the channels of the SCCS, driving the contents out of the platelets and into the surrounding media.

Platelet Adhesion. On the vessel wall, collagen, von Willebrand factor (vWF), and fibronectin are the adhesive proteins that play the most prominent role in the adhesion of platelets to vascular subendothelium. On the exposure of collagen (eg, following a laceration or the rupture of an atherosclerotic plaque), platelet adhesion is triggered. Under conditions of high shear (flowing blood), platelet adhesion is mediated by the binding of GP Ib-V-IX receptors on platelet membranes to vWF in the vascular subendothelium.⁴⁶ Following adherence of platelets to subendothelial vWF, a conformational change in GP IIb-IIIa on platelet membrane occurs, activating this receptor complex to ligate vWF and fibrinogen. The result is the amplification of platelet adhesion and aggregation. An important interaction occurs between thrombosis and inflammation. Platelet-activating factor is synthesized and coexpressed with P-selectin on the surface of the endothelium in response to mediators such as histamine or thrombin. Platelet-activating factor interacts with a receptor on the surface of neutrophils that activates the CD11/CD18 adhesion complex, and results in adhesion of neutrophils to endothelium and to platelets. This results in the synthesis of leukotrienes and other mediators of inflammation.

Platelet Activation. Thrombin, collagen, and epinephrine can activate platelets. In response to thrombin, granules fuse with each other and with elements of the SCCS to form secretory vesicles. These vesicles are believed to fuse with the surface membrane, releasing their contents into the surrounding medium. The membranes of the secretory granules become incorporated into the platelet surface membrane.

Platelet Aggregation. Following activation, GP IIb-IIIa is expressed in active form on platelet surface, serving as the final common pathway for platelet aggregation regardless of inciting stimulus. This receptor binds exogenous calcium and fibrinogen. GP IIb-IIIa ligates fibrinogen along with fibronectin, vitronectin, and vWF, resulting in the binding of platelets to other platelets, and ultimately the formation of the platelet plug. Collagen-induced platelet aggregation is mediated by adenosine diphosphate (ADP) and thromboxane A_2 . ADP binds to the metabotropic purine receptors P2Y1 and P2Y12, leading to transient and sustained aggregation, respectively.³⁵ Thromboxane A_2 is formed from arachidonic acid by the action of cyclooxygenase-1. It is a potent vasoconstrictor and inducer of platelet aggregation and release reactions.⁴⁶ Platelets participate in triggering the coagulation cascade by binding coagulation factors II, VII, IX, and X to membrane phospholipid, a calcium-dependent process.

Antiplatelet Xenobiotics

Aspirin. Aspirin inhibits prostaglandin H synthase (cyclooxygenase {COX}) by irreversibly acetylating a serine residue at the active site of the enzyme. Aspirin inhibition of the COX-1 isoform of this enzyme is 100–150 times more potent than its inhibition of the COX-2 isoform. The inhibition of COX-1 results in the irreversible inhibition of thromboxane A_2 formation. Because platelets can be activated by other mechanisms including thrombin, thrombosis can develop despite aspirin therapy (Chap. 39).⁹⁰

Selective COX-2 Inhibitors. Platelets express primarily COX-1 and use it to produce mostly thromboxane A_2 , which

leads to platelet aggregation and vasoconstriction. Endothelial cells express COX-2 and use it to produce prostaglandin I₂, an inhibitor of platelet aggregation and a vasodilator. Whereas aspirin and traditional (nonselective) nonsteroidal antiinflammatory medications inhibit the production of thromboxane A₂ and prostaglandin I₂ at both sites, the selective COX-2 inhibitors do not affect platelet-derived thromboxane A₂, perhaps accounting for the increase in cardiovascular events associated with long-term use of some of these xenobiotics.^{27,99}

Glycoprotein IIb-IIIa Antagonists. The GP IIb-IIIa antagonist abciximab is a chimeric human-murine monoclonal antibody that binds the GP IIb-IIIa receptor of platelets and megakaryocytes. Two synthetic ligand-mimetic antagonists have also been developed: eptifibatide and tirofiban. These parenteral antagonists are used primarily in patients undergoing percutaneous coronary interventions.⁴⁶ By blocking the fibrogen binding site of IIb-IIIa, platelet aggregation is blocked and even reversed regardless of the inciting activation. Reversible thrombocytopenia can occur within hours of initiation of these xenobiotics.⁸⁶

ADP Receptor Inhibitors. The thienopyridines clopidogrel, ticlopidine, and prasugrel antagonize platelet aggregation by irreversible inhibition of ADP binding to the P2Y₁₂ receptor. All three prodrugs are associated with TTP, as well as neutropenia and aplastic anemia.^{12,72,73} The purine analogs ticagrelor and cangrelor are direct-acting, reversible allosteric antagonists that bind to a different site on the P2Y₁₂ receptor.

Dipyridamole. The pyrimidopyrimidine derivative dipyridamole inhibits cyclic nucleotide phosphodiesterase in platelets, resulting in the accumulation of cyclic adenosine monophosphate and perhaps cyclic guanine monophosphate. It also inhibits cellular reuptake of adenosine, blocks thromboxane synthase, and inhibits the thromboxane receptor.

Xenobiotic-Induced Thrombocytopenia

Multiple xenobiotics are reported to cause thrombocytopenia, either via the formation of drug-dependent antiplatelet antibodies or as TTP. Drug-induced platelet antibodies are estimated to occur in 1 in 100,000 drug exposures. Reversible drug binding to platelet epitopes, such as GP Ib-V-IX, GP IIb-IIIa, and platelet-endothelial cell adhesion molecule-1, leads to a structural change that can form or expose a neoepitope target for antibody formation. The presence of the drug is required for antibody binding and increased platelet destruction, but there is no covalent bond (as occurs in the hapten model of penicillin binding to the erythrocyte membrane).

Thrombocytopenia can also occur as a result of spurious clumping, pregnancy, hypersplenism with cirrhosis, idiopathic thrombocytopenic purpura, heparin-induced thrombocytopenia ([Chap. 60](#)), bone marrow toxicity, and TTP. After excluding these conditions and nontherapeutic exposures, a systematic literature search updated annually lists more than 1000 cases reported in English involving more than 150 xenobiotics. [Table 22–7](#) lists the xenobiotics appearing in multiple cases, satisfying criteria for probable to definite causality including drug rechallenge. Nevertheless, a common clinical problem is to distinguish drug-induced thrombocytopenia from idiopathic thrombocytopenic purpura in a patient on multiple medications who develops thrombocytopenia. In the absence of validated laboratory assays for drug-dependent platelet antibodies other than heparin, diagnosis still depends on the clinical course following drug discontinuation and perhaps rechallenge. Large databases provide some guidance regarding past reported experience.^{37,60,82} Severe (<20,000 platelets/mm³), or acute transient thrombocytopenia are more likely to be drug-induced.¹⁰

TABLE 22–7. Xenobiotics Reported to Cause Thrombocytopenia as a Result of Antiplatelet Antibodies^a

Abciximab
APAP
Aminoglutethimide
Aminosalicylic acid
Amiodarone
Amphotericin B
Carbamazepine
Cimetidine
Danazol
Diclofenac

Digoxin
Dipyridamole
Eptifibatide
Famotidine
Furosemide
Gold salts
Heparin
Imipenem-cilastatin
Indinavir
Levamisole
Linezolid
Meclofenamic acid
Nalidixic acid
Orbofiban
Oxprenolol
Phenytoin
Piperacillin
Procainamide
Quinidine
Quinine
Rifampin
Tirofiban
Trimethoprim-sulfamethoxazole
Valproate
Vancomycin

^aXenobiotics reported in at least two cases to have definitely caused immune thrombocytopenia or in at least five cases to have probably caused immune thrombocytopenia following therapeutic use.

Data adapted from George JN, Raskob GE, Shah SR, et al: Drug-induced thrombocytopenia: a systematic review of published case reports. *Ann Intern Med.* 1998;129:886–890; Li X, Swisher KK, Vesely SK, George JN: Drug-induced thrombocytopenia: an updated systematic review. *Drug Safety.* 2007;30:185–186 and <http://w3.ouhsc.edu/platelets>; accessed June 24, 2013.

In patients administered the sensitizing agent de novo, 5 to 7 days are typically required for the development of the immune response. During rechallenge, thrombocytopenia can develop within 12 hours.¹⁰ Interestingly, the unique ability of GP IIb/IIIa inhibitors such as abciximab to cause thrombocytopenia within hours of first use suggests the presence of preformed antibodies directed against platelet epitopes, perhaps accounting for ex vivo clumping of platelets observed in

approximately one out of 500 normal patients.⁸³ Clinically, fever, chills, pruritus, and lethargy may occur. The onset of life-threatening bleeding may be abrupt. Hemorrhagic vesicles may be seen in the oral mucosa. Laboratory investigations will demonstrate an absence of platelets on peripheral smear, prolongation of the bleeding time, deficient clot retraction, and an abnormal prothrombin consumption test. Bone marrow aspiration will demonstrate normal or increased numbers of megakaryocytes and immature forms. Treatment includes the transfusion of blood products, glucocorticoids, and the withdrawal of the offending xenobiotic.¹⁰

Thrombotic Thrombocytopenic Purpura. TTP is characterized by the triad of microangiopathic hemolytic anemia, severe thrombocytopenia, and fluctuating neurologic abnormalities.⁶⁶ Fever and acute kidney injury are also common, although overt kidney failure is rare. The hallmark is the presence of platelet aggregates throughout the microvasculature, without fibrin clot, unlike the fibrin-rich thrombi seen in disseminated intravascular coagulation or the hemolytic uremic syndrome. In the acquired form, drug-induced autoantibodies inactivate a circulating zinc metalloprotease ADAMTS13, thereby blocking its ability to depolymerize large multimers of vWF and leading to platelet clumping.^{8,9,12,100} Plasma exchange with fresh frozen plasma replenishes ADAMTS13 and removes the inhibitory antibodies. Prior to understanding of the molecular mechanism, other causes of microvascular hemolysis with thrombocytopenia were often confused with TTP. These causes included hemolytic uremic syndrome due to shiga toxin, the HELLP syndrome of pregnancy, Rocky Mountain spotted fever, and paroxysmal nocturnal hemoglobinuria. Also included were cases secondary to xenobiotics such as cyclosporine, cocaine, gemcitabine, mitomycin C, and cisplatin, in which ADAMTS13 antibodies are not present.^{31,100}

Heparin-Induced Thrombocytopenia. An immune response to both unfractionated and low-molecular weight heparin, manifested clinically by the development of thrombocytopenia and, at times, venous thrombosis, is now recognized to result from IgG antibodies against platelet factor 4, a heparin-binding chemokine.¹ The diagnosis is confirmed by testing for these antibodies. The heparin–platelet factor 4 antibody complex results in the release of procoagulant microparticles which release tissue factor, provide an anionic phospholipid membrane surface on which clotting cascade complexes assemble, and can lead to paradoxical thrombosis, which can be limb- or life-threatening^{55,56} (Chap. 60).

SUMMARY

- The mechanisms of toxic injury to the blood are extremely varied, reflecting the complexity of this vital fluid.
- Virtually all xenobiotics come into contact with blood, and have the potential to disrupt its essential functions of oxygen transport, gas exchange, signaling, host defense, and hemostasis.
- Xenobiotics may directly injure mature cells, or prohibit their development by injuring the stem cell pool.
- Oxygen transport can be disrupted in several distinct ways, including oxidation of the heme iron, protein globin chain disruption, and shift of the oxygen-hemoglobin dissociation curve and hemolysis.
- A common theme in hematologic toxicity is the perturbation of homeostatic equilibria that exist between cell proliferation and apoptosis, between immune activation and suppression, or between thrombophilia and thrombolysis.

23 HEPATIC PRINCIPLES

Kathleen A. Delaney

The liver plays an essential role in metabolic homeostasis. Hepatic functions include the synthesis, storage, and breakdown of glycogen. In addition, the liver is important in the metabolism of lipids; the synthesis of albumin, clotting factors, and other important proteins; the synthesis of the bile acids necessary for absorption of lipids and lipid soluble vitamins; and the metabolism of cholesterol.^{64,159} Hepatocytes facilitate the excretion of metals, most importantly iron, copper, zinc, manganese, mercury, and aluminum, as well as the detoxification of products of metabolism, such as bilirubin and ammonia.^{32,74} Generalized disruption of these important functions results in manifestations of liver failure: hyperbilirubinemia, coagulopathy, hypoalbuminemia, hyperammonemia, and hypoglycemia.^{86,89,137} Disturbances of more specific functions result in accumulation of lipids, metals, and bilirubin, and the development of lipid-soluble vitamin deficiencies.^{64,159}

The liver is also the primary site of biotransformation and detoxification of xenobiotics. Its interposition between the gut and systemic circulation makes it the first-pass recipient of xenobiotics absorbed from the gastrointestinal tract. The liver receives blood from the systemic circulation and participates in the detoxification and elimination of xenobiotics that reach the bloodstream through other routes, such as inhalation or cutaneous absorption.^{142,159,160}

Many xenobiotics are lipophilic and inert and require chemical modification followed by conjugation to make them sufficiently water-soluble to be eliminated. The liver contains the highest concentration of enzymes involved in phase I oxidation-reduction reactions, the first stage of detoxification for many lipophilic xenobiotics. Conjugation of the reactive products of phase I biotransformation with molecules such as glucuronide facilitates excretion (**Chap. 13**). Although many xenobiotics that are detoxified in the liver are subsequently excreted in the urine, the biliary tract provides a second essential route for the elimination of detoxified xenobiotics and products of metabolism.^{32,56,160} Although phase I activation of xenobiotics is usually followed by phase II conjugation that results in detoxification, it can also lead to the production of xenobiotics with increased toxicity, which may cause injury to hepatocytes at the site of their synthesis.^{142,160}

MORPHOLOGY AND FUNCTION OF THE LIVER

Two pathologic concepts are used to describe the appearance and function of the liver: a structural one represented by the hepatic lobule and a functional one represented by the acinus. The basic structural unit of the liver as characterized by light microscopy is the hepatic lobule, a hexagon with the central hepatic vein at the center and the portal triads at the angles. The portal triad consists of the portal vein, the common bile duct, and the hepatic artery. Cords of hepatocytes are oriented radially around the central hepatic vein, forming sinusoids. In contrast, the acinus, or “metabolic lobule” is the functional unit of the liver. Located between two central hepatic veins, it is bisected by terminal branches of the hepatic artery and portal vein that extend from the bases of the acini toward hepatic venules at the apices. The acinus is subdivided into three metabolically distinct zones. Zone 1 lies near the portal triad, zone 3 lies near the central hepatic vein, and zone 2 is intermediate.^{64,159} **Figure 23–1** illustrates the relationship of the structural and functional concepts of the liver.

FIGURE 23–1. The acinus is defined by three functional zones. Specific contributions of each zone to the biotransformation of xenobiotics reflect various metabolic factors that include differences in oxygen content of blood as it flows from the oxygen-rich portal area to the central hepatic vein, differences in glutathione content, different capacities for glucuronidation and sulfation, and variations in content of metabolic enzymes such as CYP2E1. The hepatic lobule (not shown) is a structural concept, a hexagon with the central vein at the center surrounded by six portal areas that contain branches of the hepatic artery, bile duct, and portal vein. Injury to hepatocytes that is confined to zone 3 is called “centrilobular” because in the structure of the lobule, zone 3 encircles the central vein, which is the center of the hepatic lobule.

Approximately 75% of the blood supply to the liver is derived from the portal vein, which drains the alimentary tract, spleen, and pancreas. This blood is enriched with nutrients and other absorbed xenobiotics and is poor in oxygen. The remainder of the hepatic blood flow comes from the hepatic artery, which delivers well-oxygenated blood from the systemic circulation. Blood from the hepatic artery and portal vein mixes in the sinusoids, coming in close contact with cords of hepatocytes before it exits through small fenestrations in the wall of the vein.¹⁷⁵ Oxygen content diminishes several fold as blood flows from the portal area to the central hepatic vein.⁶⁴

There are six types of cells in the liver. Hepatocytes and bile duct epithelia make up the parenchyma. Cells found in the vicinity of the sinusoids include endothelial cells, fixed macrophages (Kupffer cells), hepatic stellate cells (so-called Ito cells), and a large population of lymphocytes that roam the sinusoids. The sinusoidal lining formed by endothelial cells is thin and fenestrated, allowing transfer of fluid, chylomicrons, and proteins across the space of Disse, an extrasinusoidal

space filled with microvilli.¹⁷⁵ Kupffer cells remove particles and cell debris that include bacteria and endotoxin from the portal circulation. They also clear many biologically active substances from the systemic circulation.¹⁶ When immunologically activated by xenobiotics, Kupffer cells contribute to the generation of oxygen free radicals^{141,178} and may also participate in the production of autoimmune injury to hepatocytes, including activation of hepatic stellate cells.^{36,73,141} Hepatic stellate cells are primary sites for the storage of fat and vitamin A.^{48,58} In a quiescent state they spread out between the sinusoidal endothelium and hepatic parenchymal cells. Filled with microtubules and microfilaments, they project cytoplasmic extensions that contact several cell types.^{48,58} Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are crucial to the development of hepatic fibrosis.^{10,46} The liver lymphocyte population is enriched with natural killer (NK) or pit cells, which play a key role in host defense by actively lysing tumor cells and cells infected by viruses^{23,47} (Fig. 23–2). Evidence from animal models suggests that NK cells selectively kill activated stellate cells, inhibiting the development of liver fibrosis.^{46,47}

FIGURE 23–2. Blood flowing through the hepatic sinusoids is separated from hepatocytes by fenestrated endothelium that allows passage of many substances across the space of Disse. This figure shows six types of cells found in the liver and their localization in relation to the sinusoid. Stellate cells are fat storage cells that promote fibrosis when activated.⁴⁶ Kupffer cells are fixed macrophages that participate in immune surveillance and are a source of free radicals when activated. Natural killer cells are lymphocytes that float freely in the sinusoids, scavenging tumor and virus infected cells.²³ Hepatocytes and bile epithelial cells form the hepatic parenchyma.

Bile acids, organic anions, bilirubin, phospholipids, xenobiotics, and other molecules excreted in bile are actively transported across the hepatocyte plasma membrane into the bile canaliculi at sites that have specificity for acids, bases, and neutral xenobiotics.¹²¹ Tight junctions separate the contents of the bile canaliculi from the sinusoids and hepatocytes, maintaining a rigid and functionally necessary compartmentalization. Bile acids use three active transport systems: a sodium-dependent bile salt transporter in the sinusoidal membrane, an adenosine triphosphate (ATP)-dependent bile salt carrier in the canalicular membrane, and a canalicular membrane transport site driven by the membrane voltage potential.^{79,121} Xenobiotics bound to glucuronide are substrates for the bile acid transport systems and are actively secreted into bile. Xenobiotics with molecular weights greater than 500 Da are also preferentially secreted into bile. Like the transport and concentration of constituents from the sinusoids and hepatocytes, the flow of bile through the canaliculi is also an active process facilitated by ATP-dependent contractions of actin filaments that encircle the canaliculi.^{79,121,171}

The enterohepatic circulation of bile acids and some vitamins plays a crucial role in their conservation. Unfortunately, this physiologically important process impedes the fecal elimination of some xenobiotics by reabsorbing and returning them back into the systemic circulation, prolonging their apparent half-lives and toxicity. Xenobiotics that have low molecular weights and are not ionized at intestinal pH, such as methylmercury, phencyclidine, and nortriptyline, are most likely to be reabsorbed.^{32,140}

TYPES OF HEPATIC INJURY

Due to its location at the end of the portal system and its substantial complement of biotransformation enzymes, the liver is especially vulnerable to toxic injury. The pathological spectrum of liver injury includes combinations of hepatocellular necrosis with focal or generalized lysis of hepatocytes and elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT); hepatitis associated with inflammatory cellular infiltrates and varied elevation of hepatocellular

enzymes; cholestasis with pruritus, jaundice, and insignificant elevations of hepatocellular enzymes; steatosis caused by intracellular deposits of fat; apoptosis, the formation of shrunken, nonfunctioning, eosinophilic bodies; and fibrosis.¹⁵⁹

FACTORS THAT AFFECT THE ANATOMIC LOCALIZATION OF HEPATIC INJURY

Hepatocellular necrosis that occurs near the portal vein is called periportal, or zone 1 necrosis. The term centrilobular or zone 3 necrosis refers to injury that surrounds the central hepatic vein. **Figure 23–3** shows centrilobular necrosis caused by exposure to bromobenzene. Metabolic characteristics of the zones of the acinus have important relevance to the anatomic distribution of toxic liver injury. Because of its location in the periportal area, zone 1 has a two-fold higher oxygen content than zone 3. Hepatic injury that results from the metabolic production of oxygen free radicals predominates in zone 1. Allyl alcohol, an industrial chemical that is metabolized to a highly reactive aldehyde, is associated with oxygen dependent lipid peroxidation injury to hepatocytes in zone 1.⁶ The tendency for centrilobular or zone 3 accumulation of fat in patients with alcoholic steatosis is attributed to the effect of relative hypoxia in the central vein area on the oxidation potential of the hepatocyte.^{9,95} The availability of substrates for detoxification and the localization of enzymes involved in biotransformation also affect the site of injury. Zone 1 has a higher concentration of glutathione, whereas zone 3 has a greater capacity for glucuronidation and sulfation.¹⁶³ Zone 3 has higher concentrations of alcohol dehydrogenase, which may lead to increased production of its toxic metabolite acetaldehyde at centrilobular sites.^{31,95,101} Zone 3 also has high concentrations of cytochrome oxidase CYP2E1, which converts many xenobiotics including acetaminophen (APAP), nitrosamines, benzene, and carbon tetrachloride (CCl_4) to reactive intermediates that may cause centrilobular injury. Although CCl_4 can be metabolized to a highly reactive oxygen free radical in zone 1, it primarily injures zone 3 for the following reasons:^{18,36,96} CCl_4 is metabolized by CYP2E1 in zone 3 to a trichloromethyl free radical ($\cdot\text{CCl}_3$) that can form covalent bonds with cellular proteins, cause lipid peroxidation, or spontaneously react with oxygen to form the more highly reactive trichloromethyl peroxy radical ($\text{CCl}_3\text{OO}\cdot$).^{18,36,96} Higher oxygen tension in zone 1 fosters the formation of $\text{CCl}_3\text{OO}\cdot$, which is rapidly detoxified by glutathione. Since the less reactive $\cdot\text{CCl}_3$ that predominates in zone 3 is not readily detoxified by glutathione, zone 3 incurs the greater amount of injury. Hyperbaric oxygen increases the oxygen tension throughout the liver and decreases liver injury caused by CCl_4 , possibly by increasing the formation of $\text{CCl}_3\text{OO}\cdot$ in zone 3, which is then efficiently detoxified by glutathione.^{18,160} The observed effects of isoniazid (an inhibitor of the enzyme CYP2E1) and chronic ethanol intake (an inducer of the CYP2E1 gene) on injury in cell cultures from periportal and centrilobular areas exposed to CCl_4 support the association of CCl_4 injury with the localization of CYP2E1 activity. Acute exposure to isoniazid significantly decreases the injury associated with exposure of zone 3 cells to CCl_4 , whereas chronic treatment with ethanol significantly enhances injury.⁹⁶

FIGURE 23–3. Centrilobular necrosis in a rat liver caused by bromobenzene administration. Note the polymorphonuclear leukocyte infiltration (arrow) surrounded by vacuolated hepatocytes in the necrotic area. (Reprinted, with permission, from Hetu C, Dumont A, Joly JG, et al: Effect of chronic ethanol administration on bromobenzene liver toxicity in the rat. *Toxicol Appl Pharm.* 1983;67:166.)

FACTORS THAT AFFECT THE DEVELOPMENT OF HEPATOTOXICITY

Xenobiotics that produce liver damage in all humans in a predictable and dose-dependent manner are called intrinsic hepatotoxins. They include APAP, CCl₄, and yellow phosphorous. Those that cause liver damage in a small number of individuals and whose effect is not apparently predictable or dose dependent are called idiosyncratic hepatotoxins.^{50,88}

Prediction of Drug-Induced Liver Injury

Drug-induced liver injury (DILI) refers to the production of liver injury by pharmaceuticals. It is the most common apparent cause of acute liver failure in the United States.^{20,134} DILI causes 33% of terminations of clinical trials of new drugs and accounts for a majority of post-marketing withdrawals of marketed drugs.¹⁶⁹ Recent studies of DILI question the lack of dose dependency of some apparently idiosyncratic hepatotoxins.^{1,20,50,84} Analysis of a Swedish data base of patients with DILI demonstrated dose dependency, as more reported cases were associated with higher doses of drugs metabolized in the liver.⁸⁴

Prediction of DILI in any individual patient based on clinical trials is difficult because the incidence is rare.^{102,169} DILI depends largely on factors that affect host susceptibility.^{5,156} These include age, gender, diet, underlying diseases, and concurrent exposure to other xenobiotics.²⁰ Genetic factors are increasingly elucidated. Many enzymes involved in biotransformation show genetic polymorphism. Inherited variations in CYP enzymes affect susceptibility to DILI.^{55,62,87,97} Approximately 8% of Caucasians are deficient in CYP2D6, which is responsible for the metabolism of a number of pharmaceuticals, including debrisoquine (an antihypertensive first identified as the substrate of this enzyme), several antidepressants and antidysrhythmics, some opioids, and phenformin.^{87,150} Perhexiline, an antianginal marketed in Europe in the 1980s, caused severe liver injury and peripheral neuropathy in persons with an inability to metabolize debrisoquine.¹⁵⁰ The congenital disorder that results in Gilbert syndrome is characterized by impaired glucuronyltransferase. Patients demonstrate decreased glucuronidation and increased bioactivation of APAP during chronic therapeutic dosing, suggesting an increased risk of hepatic injury following ingestion of APAP.²⁹ Gastrointestinal toxicity due to irinotecan, an antineoplastic used in the treatment of colon cancer, is associated with deficiency of glucuronyltransferase.¹¹¹

Studies that compare the genomes of patients who develop hypersensitivity reactions to various drugs with those who do not show significant associations with human leukocyte antigen (HLA) alleles.^{5,27,53,99,156,164,169} Hypersensitivity reactions to abacavir are significantly associated with HLA-B*5701, such that the Food and Drug Administration now recommends HLA screening prior to the initiation of abacavir.¹⁰⁴ HLA-B*5701 is also associated with cholestatic DILI in patients taking flucloxacillin, an antibiotic marketed in Europe.²⁷ Severe hypersensitivity reactions to carbamazepine are associated with the HLA allele HLA-A*3101.¹⁰⁶ Specific HLA phenotypes are implicated in the development of cholestatic liver injury in patients exposed to amoxicillin-clavulanate.^{5,99,156} DILI in the form of elevation of the ALT occurred in 15% of patients exposed to the first-generation direct thrombin inhibitor ximelagatran, with some developing clinically significant hepatitis. This was associated with two specific HLA phenotypes DRB1*07 and DQA1*02.^{69,72}

Effects of Xenobiotics on Enzyme Function

Some xenobiotic combinations increase the possibility of hepatotoxic reactions because one xenobiotic alters the metabolism of the other, leading to the production of toxic metabolites. This is the case with combinations of rifampin and isoniazid,^{65,143} amoxicillin and clavulanic acid,^{85,128} and trimethoprim and sulfamethoxazole.² Changes in the activities of biotransformation enzymes that result in increased formation of hepatotoxic metabolites suggest increased susceptibility to hepatic injury. Chronic administration of isoniazid induces CYP2E1 activity.^{143,179} During chronic ethanol exposure, proliferation of the smooth endoplasmic reticulum in the centrilobular areas is associated with increased activity of CYP2E1.^{77,96,98} In one rat study, the administration of an average of 9.2 g/kg of ethanol in increasing doses for 4 weeks resulted in a significant increase in the extent of injury to cultured zone 3 hepatocytes when exposed to CCl₄. This was associated with a higher expression of CYP2E1 in the livers of ethanol-treated rats.⁹⁶ Bromobenzene is a xenobiotic whose metabolism and hepatotoxicity are similar to that of APAP. When administered to rats chronically exposed to ethanol, the onset of hepatotoxicity occurs more rapidly in study animals, with only a small increase in the extent of hepatic necrosis. The dose of bromobenzene required for hepatic injury to occur is not altered by pretreatment with ethanol.⁵⁹ Chronic administration of phenobarbital to rats results in a significant increase in the hepatotoxic effects of bromobenzene.¹³² In humans, hepatic toxicity caused by solvents such as CCl₄, dimethylformamide, and bromobenzene may be exacerbated by chronic exposure to ethanol.^{96,105,129,130} Whether ethanol increases the clinical risk of APAP hepatotoxicity in humans has been debated.^{80,125,145,149,182}

Availability of Substrates

The availability of substrates for detoxification may significantly affect both the likelihood and localization of hepatic injury. The metabolism of APAP illustrates the effect of glutathione concentration on the delicate balance between detoxification and the production of injurious metabolites. In healthy adults taking therapeutic amounts of APAP, approximately 90% of hepatic metabolism results in formation of the glucuronide or sulfate metabolites.¹⁶⁰ Most of the remainder undergoes oxidative metabolism to the toxic electrophile N-acetyl-p-benzoquinone imine (NAPQI) and is rapidly detoxified by conjugation with glutathione.^{21,64} Glutathione may be depleted during the course of metabolism of APAP by otherwise normal livers, or it may be decreased by inadequate nutrition or liver disease.^{87,88} Excessive amounts of APAP result in increased synthesis of NAPQI, which, in the absence of glutathione, reacts avidly with hepatocellular macromolecules. The cellular concentration of glutathione correlates inversely with the demonstrable covalent binding of NAPQI to liver cells.²¹ Centrilobular (zone 3) necrosis predominates in APAP induced hepatic injury, likely related both to the centrilobular localization of CYP2E1 and to the relatively low glutathione concentrations in zone 3 compared to the periportal areas (zone 1).⁶⁴

MECHANISMS OF HEPATIC INJURY

Several pathologic mechanisms of injury that are associated with various hepatocyte “targets” are described.^{88,159}

Immune-Mediated Liver Injury

Immune-mediated liver injury is an idiosyncratic and host-dependent hypersensitivity response to exposure to xenobiotics.^{11,20,97} Damage to the hepatocyte may be mediated by complement- or antibody-directed lysis, by specific cell-mediated cytotoxicity, or by an inflammatory response stimulated by immune complexes and complement.^{10,14,15,34,70,73,110} The antibody or cell-mediated response may be precipitated by a covalently bound xenobiotic-cell protein adduct that acts as a haptén.⁵⁶ The resultant inflammatory response provokes secondary cytokine release that may promote further cell injury by neutrophils.⁵⁶ Subsequent apoptosis appears to be partly mediated by tumor necrosis factor (TNF).¹³¹ Immune-mediated toxic hepatitis is differentiated from liver injury caused by other autoimmune disorders by the absence of self-perpetuation; that is, there is a need for continuous exposure to the xenobiotic to perpetuate the injury.^{11,97} It is also less likely to recur following withdrawal of immune suppression therapy.^{11,97}

Hypersensitivity reactions result in forms of liver injury that include hepatitis, cholestasis, and mixed disorders. Whether autoantibodies stimulated by the xenobiotic–protein adducts are in all cases the actual mediators of cell injury is not clear.^{11,91} Adducts and associated autoantibodies are demonstrated for APAP,²¹ halothane,^{14,34,154} dihydralazine,¹⁵ phenytoin,⁹¹ and germander.⁸³ In cases where the metabolite is highly unstable, an electrophilic attack may be directed against the CYP enzyme at the site of formation of the metabolite.^{14,15,95,97} Autoantibodies against the CYP2E1 enzyme have been demonstrated in halothane liver injury (Chap. 68).^{14,70} The most severe form of idiosyncratic halothane liver injury is manifest as fulminant hepatic necrosis associated with formation of adducts of its trifluoroacetyl chloride (TFA) metabolite with numerous hepatoproteins that include CYP2E1 and pyruvate dehydrogenase.^{34,70,154} Autoantibodies specifically directed against CYP enzymes are also demonstrated for dihydralazine¹⁵ and phenytoin.⁹¹ A trifluoroacetyl protein adduct similar to that associated with halothane hepatitis was detected in workers who developed hepatic necrosis following exposure to hydrochlorofluorocarbons.⁶⁰ Early reports of lymphocyte sensitization in cases of xenobiotic-mediated liver toxicity suggested that cell-mediated immunity may play a role.¹⁶⁷ Cell-mediated autoimmune mechanisms are implicated in the idiosyncratic type of halothane hepatitis and are suspected in an increasing number of models of experimental xenobiotic-mediated liver injury.^{35,167} Polymorphonucleocyte (PMN) activation and infiltration appear to be important factors in the production of cholangitis in a rat model of α -naphthyl-isothiocyanate (ANIT) liver injury. ANIT stimulates the release of cytotoxic lysosomal enzymes and oxygen free radicals by activated PMNs.¹¹⁰ Antibodies directed against circulating neutrophils decrease the extent of liver damage caused by ANIT.²⁵ NK T-cells are ubiquitous in the liver, and their possible role in the facilitation of cell-mediated autoimmune liver injury is being investigated.^{23,24,52}

Pharmaceuticals most commonly involved in autoimmune injury are nitrofurantoin and minocycline.¹¹ Drugs with hypersensitivity reactions that typically present with hepatitis include halothane,^{14,70,154} trimethoprim-sulfamethoxazole,^{2,117} anticonvulsants,⁹¹ and allopurinol.^{3,153} Drugs associated with hypersensitivity that typically present with cholestatic signs include chlorpromazine, erythromycin, penicillins, rifampin, and sulfonamides.^{79,121,167} Signs of injury typically begin 1 to 8 weeks following the initiation of the drug, although they may begin as late as 20 weeks for drugs such as isoniazid or dantrolene. The onset of signs of injury associated with the oxypenicillins may occur as late as 2 weeks after the drug is stopped.⁹⁷ In all cases, the onset is earlier when the patient is rechallenged with the drug. Antinuclear antibodies and smooth muscle antibodies are frequently present, as are eosinophilia, atypical lymphocytosis, fever, and rash. Their absence does not exclude an autoimmune mechanism of drug-associated liver injury.^{11,76,97} Liver injury characterized by the formation of hepatic granulomas may also be a consequence of hypersensitivity reactions.¹⁰⁹

Xenobiotics That Target the Biliary Tract

Xenobiotics that undergo biliary excretion are most commonly associated with jaundice in patients with hepatotoxicity.¹²¹ Xenobiotics induce cholestasis by targeting specific mechanisms of bile synthesis and flow or by damaging canalicular cells.^{54,79} Elucidations of various bile transport proteins have led to better understanding of mechanisms of cholestasis in toxic liver injury.¹²¹ Cholestasis may occur with or without associated hepatitis. The development of jaundice following hepatic necrosis is a manifestation of general failure of liver function. More discrete mechanisms that result in intrahepatic cholestasis include (a) impairment of the integrity of tight membrane junctions that functionally isolate the canaliculus from the hepatocyte and sinusoids, (b) failure of transport of bile components across the hepatocytes, (c) blockade of specific membrane active transport sites, (d) decreased membrane fluidity resulting in altered transport, and (e) decreased canalicular contractility resulting in decreased bile flow.^{13,79,121,146} Xenobiotics that specifically target bile canaliculi may lead to irreversible injury, the so-called “vanishing bile duct syndrome.”¹⁶¹ Estrogens cause intrahepatic cholestasis by altering the composition of the lipid membrane and inhibiting the rate of secretion of bile into the canaliculi.^{79,146} Rifampin impedes the uptake of bilirubin into hepatocytes. Methyltestosterone and C-17 alkylated anabolic steroids impair the secretion of bilirubin into canaliculi.⁹⁴ Cyclosporine inhibits sodium-dependent uptake of bile salts across the sinusoidal membrane and blocks ATP-dependent bile salt transport across the canalicular membrane.¹³ Floxacillin causes cholestasis with minimal inflammation or evidence of hepatocellular injury.¹⁶⁷ Exposure of rats to ANIT causes a specific injury localized to the tight junctions that separate the hepatocyte from the canaliculi. This results in reflux of bile constituents into the sinusoidal space and increased access of sinusoidal molecules to the biliary tree.^{25,79,110}

Mitochondrial Injury

Direct mitochondrial injury impairs cellular respiration and is associated with fat accumulation, diminution of ATP production, and metabolic acidosis with elevated lactate.^{82,89,122} This may involve attacks by xenobiotics on structural components of the mitochondria such as DNA, respiratory chain enzymes, and membranes. Nucleoside analogs that inhibit viral reverse transcriptase also inhibit mitochondrial DNA synthesis, leading to depletion of mitochondria.^{22,82,108,144}

Other Targets

Stimulation of Kupffer cells enhances hepatic injury. When immunologically activated by xenobiotics, Kupffer cells contribute to the generation of oxygen free radicals^{141,178} and may also participate in the production of autoimmune injury to hepatocytes, including activation of hepatic stellate cells.^{36,73,141} Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are crucial to the development of hepatic fibrosis.^{9,46} Hepatic venoocclusive disease is caused by xenobiotics that injure the endothelium of terminal hepatic venules, resulting in intimal thickening, edema, and nonthrombotic obstruction.^{81,107,113,174,176}

MORPHOLOGIC MANIFESTATIONS OF TOXIC HEPATIC INJURY

The liver responds to injury in a limited number of ways.^{67,68,88,118,159} Cells may swell (ballooning degeneration) and accumulate fat (steatosis) or biliary material. They may necrose and lyse or undergo the slower process of apoptosis, forming shrunken, nonfunctioning, eosinophilic bodies. Necrosis may be focal or bridging, linking the periportal or centrilobular areas; zonal or panacinar; or it may be massive.^{59,86,108} An autoimmune type of injury is characterized by hepatitis with a prominent plasma cell infiltrate.^{11,97,164} Injury to the bile ducts results in cholestasis.^{79,121,167} Xenobiotics that target canalicular transport proteins may cause cholestasis in the absence of injury to hepatocytes.¹²¹ Direct mitochondrial injury impairs cellular respiration and is associated with fat accumulation, diminution of ATP production, and metabolic acidosis.^{82,122} Injuries to the intima of postsinusoidal veins cause obstruction to venous flow.^{81,176} The vascular effects of cocaine may cause ischemic liver injury.^{87,165} Table 23–1 lists characteristic morphologies of hepatic injury and associated xenobiotics.

Acute Hepatocellular Necrosis

Numerous xenobiotics are associated with hepatocellular necrosis (Table 23–1). APAP is a common cause, as are herbal remedies that contain hepatotoxins, whose risks are increasingly recognized.^{37,61,116} Many halogenated hydrocarbons that include carbon tetrachloride,^{18,96} bromobenzene,^{59,132} hydrochlorofluorocarbons,⁶⁰ halothane,^{15,70,154} and antituberculous medications^{19,112,143} also produce hepatocellular necrosis. A study of more than 11,000 patients exposed to isoniazid during preventive treatment showed that the risk of hepatocellular necrosis was low, occurring in 0.1% of those starting treatment, and in 0.15% of those completing treatment.^{19,120} Risk factors for the development of hepatotoxicity from isoniazid exposure are female sex, increasing age, coadministration with rifampin, and alcoholism¹⁹ (Chap. 58). The thiazolidinedione antidiabetics troglitazone and rosiglitazone are associated with acute hepatocellular necrosis.^{44,51} Occupational exposure to solvents including dimethylformamide and CCl₄ causes dose-related hepatocellular necrosis.^{129,130}

Acute necrosis of a hepatocyte disrupts all aspects of its function. Because there is a great deal of functional reserve in the liver, hepatic function may be preserved despite the development of focal necrosis.¹⁵⁹ Extensive necrosis results in functional liver failure. The processes that lead to cell necrosis are not well known. Cell lysis is preceded by the formation of blebs in the lipid membrane and leakage of cytosolic enzymes, primarily aminotransferases and lactate dehydrogenase. Coalescence of blebs leads to rupture of the cellular membrane and acute irreversible cell death, with disintegration of the nucleus and termination of all cellular function. Prior to membrane rupture, this injury is reversible by membrane repair processes.¹¹⁰ The release of intracellular constituents attracts circulating leukocytes and results in an inflammatory response in the hepatic parenchyma. A proposed mechanism of rapid injury to the cell membrane is the initiation of a cascading lipid peroxidation reaction following attack by a free radical. The CYP2E1 enzyme has a significant potential to produce oxygen free radicals, as do activated PMNs and Kupffer cells.^{26,36,46,110,141,178} Oxidant stress is an important cause of liver injury during the metabolism of ethanol by CYP2E1. This results in cell death and the stimulation of stellate cells, which promotes fibrosis.^{31,46,159} In addition to peroxidation of membrane lipids, the oxidation of proteins, phospholipid fatty acyl side chains, and nucleosides appears to be widespread. Mitochondrial injury and resultant ATP depletion may also be associated with necrosis.^{67,103} Xenobiotics known to cause mitochondrial injury include antiretroviral drugs that inhibit the replication of mitochondrial DNA,^{22,28,108} tetracycline,¹⁴⁷ valproic acid,¹⁸⁰ hypoglycin, margosa oil, and cereulide.^{103,144}

Steatosis

Steatosis is the abnormal accumulation of fat in hepatocytes. It reflects abnormal cellular metabolism in conditions that include responses to xenobiotics. Cell injury depends on the severity of the underlying metabolic disturbance. Steatosis per se is normally well tolerated and reversible in many cases, although approximately one-third of patients with nonalcoholic steatosis may develop steatohepatitis.^{41,82} Nonalcoholic steatosis associated with obesity, insulin resistance, and the metabolic syndrome may account for many cases of cryptogenic cirrhosis.⁴¹ The β -oxidation of fatty acids depends on a steady synthesis of cellular energy in the form of ATP and takes place in the mitochondria. Mechanisms of impaired β -oxidation of fatty acids include direct inhibition or sequestration of critical cofactors such as coenzyme-A and L-carnitine.^{82,122}

Intracellular fat accumulation may also occur as a result of any one or more of the following mechanisms: impaired synthesis of lipoproteins, increased mobilization of peripheral adipose stores, increased uptake of circulating lipids, increased triglyceride production, decreased binding of triglycerides to lipoprotein, and decreased release of very-low-density lipoproteins from the hepatocytes.^{82,95} There are two light microscopic manifestations of steatosis: macrovesicular steatosis, in which the nucleus is displaced by large droplets of intracellular fat, and microvesicular steatosis, which is characterized by tiny cytoplasmic fat droplets that do not displace the nucleus. Xenobiotics associated with macrovesicular steatosis include ethanol and amiodarone. Ethanol increases the uptake of fatty acids into hepatocytes and decreases lipoprotein secretion. In addition, the increased ratio of the reduced form of nicotinamide adenine dinucleotide (NADH) to the oxidized form of nicotinamide adenine dinucleotide (NAD⁺), associated with hepatic metabolism of ethanol, decreases oxidation of fatty acids and promotes fatty acid synthesis.⁹⁵ An early pathologic lesion that occurs in alcoholic liver disease is reversible macrovesicular steatosis. Steatohepatitis is a more virulent form, characterized by ballooning degeneration of hepatocytes and apoptosis that may progress to cirrhosis.^{92,177} Mallory bodies, eosinophilic cytoplasmic deposits of keratin

filaments in degenerating hepatocytes, are also common microscopic findings in alcoholic liver disease.^{9,95,100,101} Amiodarone hepatic toxicity resembles that of alcoholic hepatitis, with steatosis, Mallory bodies, and potential for progression to cirrhosis.⁸⁷ Lamellated intralysosomal phospholipid inclusion bodies are specific for amiodarone toxicity.¹³⁶ Figure 23–4 shows macrovesicular steatosis with Mallory bodies caused by amiodarone.

FIGURE 23–4. Macrovesicular steatosis associated with administration of amiodarone. The small arrow indicates the presence of Mallory bodies. The large arrow points to accumulated intracellular fat. (Note that the nuclei are displaced.) Polymorphonuclear leukocytes (P) are also present. (Reprinted, with permission, from Lee WM. Drug-induced hepatotoxicity. *N Engl J Med.* 1995;333:1118.)

Steatosis Associated with Mitochondrial Dysfunction. Microvesicular steatosis is caused by severe impairment of β -oxidation of fatty acids. Valproic acid causes mild elevations of aminotransferases in approximately 11% of patients, usually during the first few months of therapy. The earliest pathologic lesion that signals progression of liver injury is microvesicular steatosis, which occurs in the absence of necrosis. An association between deficiency of carnitine, microsteatosis, and the development of hyperammonemia is observed in children treated with valproic acid.^{12,126,166} A small percentage of patients progress to fulminant hepatic failure characterized by centrilobular necrosis.¹⁸⁰ The incidence of fatal hepatocellular injury is highest in children, approaching 1 in 800 children younger than 2 years of age.¹²⁶ Other mechanisms of impaired β -oxidation of fatty acids include processes that disrupt cellular ATP production, either directly by xenobiotics such as sodium azide or cyanide that inhibit electron transport in the respiratory chain, by xenobiotics that increase permeability of mitochondrial membranes and degrade the proton gradient that is critical to ATP synthesis, or by xenobiotics that uncouple oxidative phosphorylation.^{93,144,147} Microvesicular steatosis is described in patients taking antiretrovirals such as zidovudine, zalcitabine, and didanosine.^{28,155,158} In all cases, metabolic acidosis with elevated lactate is a prominent biochemical feature.^{28,144} The nucleoside analog fialuridine caused severe hepatotoxicity during a study of its use in the treatment of chronic hepatitis B infection. Microscopic examinations of liver specimens in these cases showed marked accumulation of fat with minimal necrosis or structural injury. Severe acidosis and failure of hepatic synthetic function suggested failure of cellular energy production. Mitochondria examined under the electron microscope were demonstrably abnormal.¹⁰⁸ Figure 23–5 demonstrates microvesicular steatosis in a patient with fialuridine hepatotoxicity. High doses of tetracycline produce microvesicular steatosis associated with moderate elevations of aminotransferases, markedly prolonged prothrombin time (PT), and progression to fulminant hepatic failure.¹⁴⁷ Microvesicular steatosis attributed to failure of mitochondrial energy production was reported in a fatal case of *Bacillus cereus* food poisoning, where high concentrations of the bacterial emetic toxin cereulide are found in the bile and liver. In this case, microvesicular steatosis is associated with extensive hepatocellular necrosis.¹⁰³ Other xenobiotics that cause mitochondrial failure are hypoglycin, the cause of Jamaican vomiting sickness, aflatoxin, and margosa oil.¹⁴⁴ Steatosis is also observed following exposure to the industrial solvent dimethylformamide. Liver biopsies in patients with acute illness show focal hepatocellular necrosis and microvesicular steatosis. More prolonged, less symptomatic exposures result in significant macrovesicular steatosis with mild aminotransferase elevations.^{129,130}

FIGURE 23–5. This figure shows severe microvesicular steatosis in a patient treated with fialuridine. Note the central location of the nuclei. (Reprinted, with permission, from McKenzie R, Fried MW, Sallie R, et al. Hepatic failure and lactic acidosis due to fialuridine, an investigational nucleoside analogue for chronic hepatitis B. *N Engl J Med.* 1995;333:1099.)

Venoocclusive Disease

Hepatic venoocclusive disease is caused by xenobiotics that injure the endothelium of terminal hepatic venules, resulting in intimal thickening, edema, and nonthrombotic obstruction. Central and sublobular hepatic veins may also become edematous and fibrosed. There is intense sinusoidal dilation in the centrilobular areas that is associated with liver cell atrophy and necrosis.¹⁷⁴ The gross pathologic appearance is that of a “nutmeg” liver.^{81,176} Massive hepatic congestion and ascites ensue.^{81,135} Hepatic venoocclusive disease is rapidly fatal in 15% to 20% of cases. It is associated with exposure to pyrrolizidine alkaloids found in many plant species including *Symphytum* (comfrey tea),^{172,176} *Heliotrope*, *Senecio*, and *Crotalaria*.⁸¹ It has occurred in epidemic proportions, in South Africa after the ingestion of flour contaminated with ragwort (*Senecio*), in Jamaica after the ingestion of “bush teas” (*Crotalaria* spp), and in India and Afghanistan when food was contaminated with *Heliotropium lasiocarpine* and *Crotalaria*.^{17,113} A rapidly progressive form has been reported in bone marrow transplant patients following high-dose treatment with cyclophosphamide.¹⁰⁷

Chronic Hepatitis

A form of toxic hepatitis that clinically resembles autoimmune hepatitis occurs with the chronic administration of drugs such as methyldopa, allopurinol, nitrofurantoin, propylthiouracil, nafcillin, dantrolene, and diclofenac.^{3,7,11,71,89,133,148,157} Many cases are associated with positive antinuclear antibody (ANA), smooth muscle antibody (SMA), and hyperglobulinemia. Jaundice is prominent and hepatocellular enzymes are elevated 5- to 60-fold. Liver biopsy commonly reveals intrahepatic cholestasis, as well as centrilobular inflammation.^{11,97}

Granulomatous hepatitis is characterized by infiltration of the hepatic parenchyma with caseating granulomata. At least 60 drugs are associated with this disorder. Fever and systemic symptoms are common, and 25% of patients have splenomegaly. Liver enzymes are mixed, reflecting variable degrees of cholestasis and hepatocellular injury. Eosinophilia occurs in 30% as an extrahepatic manifestation of drug hypersensitivity. Continued exposure may result in a more severe form of liver disease. Small vessel vasculitis, which may involve the skin, lungs, and kidney, is a disturbing sign associated with increased mortality.^{88,109,181} Table 23–1 lists a number of the xenobiotics that are implicated in this disorder.

Cirrhosis

Cirrhosis is caused by progressive fibrosis and scarring of the liver, which results in irreversible hepatic dysfunction and portal hypertension. This causes shunting of blood away from hepatocytes and subsequent hepatocellular dysfunction. Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are deposited in the space of Disse and are crucial to the development of hepatic fibrosis.^{46,159} The development of fibrosis requires inflammation. Reactive oxygen species derived from lipid peroxidation, reduced NADPH, and apoptotic cells are important inflammatory stimuli that activate stellate cells.⁴⁶ In alcoholic cirrhosis, acetaldehyde and tumor necrosis factor provide a cytokine-mediated inflammatory stimulus.^{9,95,159} Chronic ingestion of excessive amounts of vitamin A (25,000 units/day for 6 years or 100,000 units/day for 2.5 years) results in cirrhosis. An increase in the fat content of the sinusoidal stellate cells with

increasing degrees of collagen formation are characteristic lesions that occur early in vitamin A toxicity (Chap. 47). Portal hypertension may be early and striking.⁴⁹ Like vitamin A, methyldopa and methotrexate also cause a slow progressive development of cirrhosis with few clinical symptoms.^{90,173} Methotrexate-induced hepatic fibrosis is dose dependent. Risk factors include associated alcohol intake and preexisting liver disease. Reduced dosing has largely eliminated the risk of the development of cirrhosis in patients receiving methotrexate.^{67,173}

Hepatic Tumors

There is persuasive evidence that the use of oral contraceptive steroids increases the risk of hepatic adenomas.⁷⁵ Oral contraceptives also increase the overall risk of hepatocellular carcinoma; however, the number of cases associated with estrogen therapy is low.⁶³ Anabolic steroids are rarely associated with the development of both benign and malignant hepatic tumors.⁴⁰ Angiosarcoma is strongly associated with exposure to vinyl chloride, in addition to arsenic, thorium dioxide, and androgenic hormones.³⁸

Hepatic Injury Associated with Plants and Herbs

In addition to the venoocclusive disease associated with pyrrolizidine alkaloids described above, herbal remedies are increasingly recognized as a cause of acute hepatocellular injury. Numerous plants or plant products are known or suspected to cause hepatic injury (Chaps. 45 and 121).^{33,37,61,83,116}

CLINICAL PRESENTATION OF TOXIC LIVER INJURY

Clinical presentations of toxic liver injury range from indolent, often asymptomatic progression of impairment of hepatic function to rapid development of hepatic failure. Jaundice and pruritus are due to increased concentrations of bile acids and bilirubin in the blood. Failure of hepatocellular synthetic function results in bleeding due to coagulopathy and edema due to hypoalbuminemia. Encephalopathy may be due to hypoglycemia, impaired neurotransmission, or accumulation of toxic products of metabolism such as ammonia. Fever may occur with autoimmune-mediated liver injury. Impaired hepatic blood flow results in familiar manifestations of portal hypertension such as caput medusa, splenomegaly, ascites, and varices. Spider angiomas and gynecomastia also occur due to altered estrogen metabolism.¹⁵⁹

Acute Liver Failure

Acute liver failure is defined as a rapid onset of liver injury progressing over 2 to 3 weeks that results in altered mental status, vasodilation, kidney and pulmonary failure, frequent infection, and a poor outcome without transplantation.^{45,90,137,159} Complications from acute liver failure include encephalopathy, cerebral edema, coagulopathy, kidney dysfunction, hypoglycemia, hypotension, acute respiratory distress syndrome, sepsis, and death. The encephalopathy associated with chronic liver disease should be considered separately from the rapidly progressive disorder of acute liver failure.^{38,137} In some cases, a patient may progress from health to death in as little as 2 to 10 days.^{42,87,103,119,137} Table 23–2 emphasizes the clinical progression of encephalopathy as acute liver failure develops. The prognosis of acute liver failure is related to the time that passes between the onset of jaundice and the onset of encephalopathy. Perhaps surprisingly, a better prognosis is associated with shorter (2 to 4 weeks) jaundice-to-encephalopathy intervals.^{137,138} Most cases are caused by xenobiotics or viral hepatitis. Acute liver failure is usually associated with extensive necrosis, although it may occur in the absence of demonstrable necrosis following exposures to xenobiotics that injure mitochondria.^{103,108,158} Some xenobiotics that are associated with acute liver failure are shown in Table 23–1.

TABLE 23–2. Stages of Hepatic Encephalopathy

<i>Clinical Stage</i>	<i>Mental Status</i>	<i>Neuromotor Function</i>
Subclinical	Normal physical examination	Subtle impairment of neuromuscular function → driving or work injury hazard
I	Euphoric, irritable, depressed, fluctuating mild confusion, poor attention, sleep disturbance	Poor coordination; asterixis alone
II	Impaired memory, cognition, or simple mathematical tasks	Slurred speech, tremor, ataxia
III	Difficult to arouse, persistent confusion, incoherent	Hyperactive reflexes, clonus, nystagmus
IV	Coma; may respond to noxious stimuli	Decerebrate posturing; Cheyne-Stokes respirations; pupils are reactive and the oculoccephalic reflex is intact; signs of ↑ intracranial pressure

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a complex disorder that affects both cognitive and neuromuscular functions of the central nervous system.^{8,138,139} Cognitive changes range from barely discernible impairment evident only on psychometric testing to confusion, stupor and coma. Neuromuscular signs include slowed motor responses, asterixis, myoclonus, and rigidity.^{8,139} HE is potentially fully reversible, even in cases of deep coma.^{43,139} Table 23–2 lists the clinical stages of acute HE. Ammonia concentrations are elevated in 60% to 80% of patients with HE.¹³⁹ The demonstration that ammonia is not elevated in many cases suggests that there are other pathogenic etiologies and the etiology is multifactorial.¹³⁸ Disruption of central neurotransmitter regulation including dopamine receptor binding may contribute.¹⁷⁰ There is evidence that liver failure is associated with the accumulation of substances that stimulate central benzodiazepine receptors, leading to enhancement of γ -aminobutyric acid transmission.^{4,139} Other toxins that include mercaptans, phenol, and manganese may also play a role.¹³⁹ Inflammation and infection is also proposed as an important precipitant.¹⁵² Ammonia is produced in the colon by bacterial breakdown of ingested proteins then transported to the liver via the portal circulation where it is detoxified to glutamine and urea by urea cycle enzymes.^{8,123,138} Processes that raise central nervous system ammonia concentrations include infection, hypokalemia, alkalosis, increased muscle wasting, volume depletion, azotemia, and gastrointestinal bleeding.^{8,138,139,152} Alkalosis and hypokalemia facilitate conversion of NH_4^+ to NH_3 , which moves more easily across the bowel wall and the blood–brain barrier. Acidification of the bowel by bacterial breakdown of lactulose creates a hostile environment for ammonia-producing bacteria and constructs a gradient that favors entrapment of ammonia in the bowel.^{123,138} In a study of lactulose alone versus placebo, over a 14-month period 19.6% of patients on lactulose had recurrent HE, compared with 48.6% of patients on placebo.¹⁵¹ A nonabsorbed broad-spectrum antibiotic rifaximin has been shown to decrease the recurrence of HE in cirrhotic patients, presumably by decreasing the numbers of urease-containing colonic bacteria that produce ammonia. Recurrence rates at 6 months were 22.1% in the rifaximin groups versus 46.8% in the placebo group. In this study, 90% of the patients in each group were also on lactulose.⁸

Flumazenil has been proposed to treat HE. Although it is clear that benzodiazepines can make encephalopathy worse, studies of the use of flumazenil to reverse encephalopathy show conflicting results.^{4,137} Although there is no clear evidence that all patients will benefit from flumazenil, some individuals may benefit for a short time. Certainly, the administration of benzodiazepines should be avoided.⁴

EVALUATION OF THE PATIENT WITH LIVER DISEASE

The history is critical in establishing the etiologic diagnosis of the patient with liver disease. A medication history should include careful investigation of nonprescription xenobiotics, especially APAP and the possible use of alternative or complementary therapies including herbal therapies. Nearly any chronically used medications should be suspect. An occupational history may indicate exposure to vinyl chloride (plastics industry), dimethylformamide (leather industry), or other industrial solvents. Table 23–3 lists occupational exposures that result in liver injury. Alcohol abuse is a common cause of acute hepatitis and the most common cause of cirrhosis in the USA.^{9,95,101} A history of male homosexual contacts, health care occupation, or intravenous drug use indicates the possibility of hepatitis B and C. Recent travel to a developing

country suggests the possibility of hepatitis A. In patients with significant pain, the possibility of cholelithiasis should be considered.¹⁵⁹

TABLE 23–3. Occupational Exposures Associated with Liver Injury

<i>Xenobiotic</i>	<i>Type of Injury</i>
Arsenic	Cirrhosis, angiosarcoma
Beryllium	Granulomatous hepatitis
Carbon tetrachloride	Acute necrosis
Chlordecone	Minor hepatocellular
Copper salts	Granulomatous hepatitis, angiosarcoma
Dimethylformamide	Steatohepatitis
Methylenedianiline	Acute cholestasis
Phosphorus	Acute necrosis
Tetrachloroethane	Acute, subacute necrosis
Tetrachloroethylene	Acute necrosis
Toluene	Steatosis, minor hepatocellular
Trichloroethane	Steatosis, minor hepatocellular
Trinitrotoluene	Acute necrosis
Vinyl chloride	Acute necrosis, fibrosis, angiosarcoma
Xylene	Steatosis, minor hepatocellular

Biochemical Patterns of Liver Injury

There are two basic biochemical patterns associated with liver injury induced by xenobiotics. The hepatocellular pattern is characterized by elevation of liver aminotransferases due to the injury of hepatocytes by apoptosis or necrosis.¹¹⁸ The cholestatic pattern is characterized by elevation of the serum alkaline phosphatase concentration and bilirubin and usually results from injury or functional impairment of the bile ductules.⁵⁴ Processes associated with intrahepatic cholestasis in the absence of hepatitis may not lead to significant aminotransferase elevation.^{117,128,181}

Aminotransferases. Laboratory tests are helpful, and certain patterns may be suggestive of specific etiologies (Table 23–4). Elevation of hepatocellular enzymes, especially the AST and ALT, indicates hepatocellular injury, and within a given clinical context, has useful diagnostic significance. Aminotransferases may be increased up to 500 times normal when hepatic necrosis is extensive, such as in severe acute viral or toxic hepatitis.^{86,124} The degree of elevation does not always reflect the severity of injury because concentrations may decline as liver failure progresses. Only moderately elevated, or occasionally normal, aminotransferase concentrations occur in some patients with hepatic failure caused by mitochondrial failure, cirrhosis, or venoocclusive disease.^{49,81,108,180} Aminotransferase concentrations may be normal or only slightly elevated in processes associated with intrahepatic cholestasis in the absence of hepatitis.^{117,128,181} In alcoholic liver disease, in contrast to other forms of hepatitis, the AST concentration is typically two to three times greater than the ALT. Elevation of either of these enzymes greater than 300 IU/L is inconsistent with injury caused by ethanol.^{100,124} During acute extrahepatic obstruction of the biliary tract, the AST or ALT may be as high as 1000 IU/L, indicating inflammation caused by reflux of bile acids into the biliary tree.¹²⁴ The measurement of γ -glutamyl transpeptidase (GGTP) is not very useful because it is present throughout the liver and its elevation is often nonspecific.¹²⁴

TABLE 23–4. Laboratory Tests That Evaluate the Liver

Disorder	Alkaline Phosphatase	AST, ALT	Albumin	Prothrombin Time	Bilirubin	Ammonia	Anion Gap
Hepatocellular necrosis, acute focal (hepatitis)	N or ↑	↑↑↑	N	N or ↑	↑↑	N	N
Hepatocellular necrosis, acute massive	N or ↑	↑↑↑	N	↑↑	↑↑↑	↑↑	↑
Chronic infiltrative disease (tumor, fatty liver)	↑↑↑	↑	N	N	N	N	N
Acute mitochondrial failure	N or ↑	N or ↑	N	↑↑	↑	↑↑	↑↑↑
Cholelithiasis	↑	N or ↑	N	N	N or ↑	N	N
Cholestasis	↑↑	N or ↑	N	N	↑	N	N
Chronic hepatitis	N or ↑	↑	N or ↓	N	N or ↑	N or ↑	N
Cirrhosis	N or ↑	↑	↓	N or ↑	N or ↑	N or ↑	N

↑ = increase; ↓ = decrease; N = normal.

Alkaline Phosphatase. In patients with cholestasis, bile acids stimulate the synthesis of alkaline phosphatase by hepatocytes and biliary epithelium in response to a number of pathologic processes in the liver. Elevations of the alkaline phosphatase as great as 10-fold may occur with infiltrative liver diseases but are most commonly associated with extrahepatic obstruction.¹²⁴ Although the alkaline phosphatase may be normal or elevated only minimally in hepatocellular injury, it is unusual for obstruction to occur without some elevation of the alkaline phosphatase. Elevations of alkaline phosphatase and GGTP parallel each other in diseases of the biliary tract.¹²⁴

Bilirubin. Elevation of conjugated (direct) bilirubin implies impairment of secretion into bile, whereas elevation of unconjugated (indirect) bilirubin implies impairment of conjugation. Unconjugated hyperbilirubinemia also occurs during hemolysis and in rare disorders of hepatic conjugation such as Gilbert or Crigler-Najjar syndromes. Except in cases of pure unconjugated hyperbilirubinemia, the fractionation of bilirubin in the case of hepatobiliary disorders does not have any important diagnostic utility, and it will not distinguish patients with parenchymal disorders of the liver from intrinsic or extrinsic cholestasis. The presence of bilirubin in the urine implies elevation of conjugated (direct) bilirubin, which is water soluble and filtered by the glomerulus, obviating the need for laboratory fractionation.^{124,159}

Urobilinogen is produced by the bacterial metabolism of bilirubin in the bowel lumen. It is absorbed and excreted in the urine. Its presence in the urine indicates the normal excretion of bilirubin in bile, while its absence is associated with complete biliary obstruction. As a result of more modern methods of detection of complete obstruction of the biliary tract, this test is mainly of historical interest.

Serum Albumin. Quantitatively, albumin is the most important protein that is made in the liver. With a half-life as great as 20 days, the albumin is usually normal in the previously healthy patient with acute liver injury. In the absence of disorders that affect albumin, such as nephrotic syndrome, protein-losing enteropathy, or starvation, a low serum albumin concentration is a useful marker for the severity of chronic liver disease.^{124,159}

Coagulation Factors. Impairment of coagulation is a marker of the severity of hepatic dysfunction in both acute and chronic liver disease. Elevation of the PT in acute hepatitis is associated with a higher risk of hepatic failure.^{57,87,108} Unlike the case with serum albumin, the onset of coagulopathy as a consequence of impaired synthesis of coagulation factors produced in the liver is rapid. Acute changes in coagulation reflect the concentration of factor VII, which has the shortest half-life.⁶⁶ The extrinsic coagulation pathway, as measured by the PT, is affected by reductions in factors VII, IX, and X. In addition to failure of hepatic synthesis, inadequate concentrations of factors II, VII, IX, and X may also result from ingestion of warfarin anticoagulants or malabsorption of vitamin K (**Chap. 60**).

Because different thromboplastin reagents give different PT values on the same sample, the international normalized ratio (INR) was developed to normalize PT measurements in patients treated with warfarin, allowing comparisons of therapeutic outcomes across different care settings and across the literature. The INR uses the International Sensitivity Index (ISI) that is derived from a cohort of patients on stable anticoagulant therapy. It normalizes the responsiveness of a given thromboplastin reagent in comparison to a WHO reference standard that is assigned a value of 1.0.⁷⁸ There is little controversy regarding the value of the INR in comparison with the PT ratio for measuring the extent of warfarin-induced anticoagulation. In patients with liver disease, use of the INR implies a normalized correlation that does not exist and is therefore potentially misleading. Because factor deficiencies in patients with liver disease are different from those in patients on warfarin, there is considerable controversy regarding which measurement is best for patients with liver disease.^{30,66,78} Although comparison of factor concentrations in warfarin-treated patients with those with liver disease showed no difference in factor VII, there are significant differences in factors II, V, X, and fibrinogen. Comparison of the PT with INR in the evaluation of test results with three different thromboplastin reagents showed consistency among the control groups of warfarin-treated patients, but no consistency among PT or INR measurements using the same

thromboplastin reagents in patients with liver disease.⁷⁸ Because of a failure to demonstrate an advantage, liver specialists have supported the continued use of the PT to describe the degree of liver injury, lacking the availability of a single reliable standard that would help predict operative risk.^{30,78} The implication for toxicologists is that caution should be exercised in relying too heavily on published INR values that purportedly predict the severity of illness in patients with acute liver failure.

A thoughtful review of bleeding risk due to coagulopathy in chronic liver disease discussed the balance of procoagulation forces (elevated factor VIII concentrations, elevated von Willebrand factor, decreased protein C and antithrombin) and anticoagulation forces (decreased fibrinogen and other clotting factors, high tissue plasminogen activator, low platelet count). The balance is simply characterized as a seesaw effect between stimulation of thrombin generation by factor VIII and the suppression of thrombin generation by protein C. This fragile balance between procoagulation and anticoagulation may be tipped by events such as kidney failure or infection. It is not effectively characterized by the INR or the PT. The review proposed that the standard belief that patients with liver failure are “auto-anticoagulated” and not at risk of venous or arterial thrombosis is erroneous. The authors suggested that neither the PT nor the INR could predict bleeding risk in the cirrhotic patient and proposed further investigations to help identify bleeding risk and prevent or manage thrombotic events in cirrhotic patients.¹⁶²

Ammonia. Severe generalized impairment of hepatic function leads to a rise in the serum ammonia concentration as a result of impairment of hepatic detoxification of ammonia produced during catabolism of proteins.^{8,123,138} Urease-containing bacteria within the bowel, especially *Klebsiella* and *Proteus* species, are the most prominent producers of ammonia.¹³⁸ Some patients treated with valproic acid develop alterations in mental status associated with elevated ammonia concentrations in the absence of other laboratory indicators of hepatic injury.^{37,127,168} Hyperammonemia in patients on valproic acid is also commonly asymptomatic.¹¹⁵ This has been attributed to selective impairment of urea cycle enzymes ornithine transcarbamylase or carbamyl phosphate synthetase by pentanoic acid metabolites ([Chap. 48](#)). As noted above, an association between deficiency of carnitine, microsteatosis, and the development of hyperammonemia in the setting of liver failure is observed in children treated with valproic acid. This is attributed to impairment of carnitine-dependent β -oxidation of sodium valproate and free fatty acids in the mitochondria.^{12,126,166}

Other Laboratory Tests

Serologic studies for the presence of markers of hepatitis A, B, and C should be obtained routinely in patients with hepatitis. In the patient with severe liver injury, hypoglycemia is a major concern because of impairment of glycogen storage and gluconeogenesis. Hyperglycemia also occurs as a result of the inability of the liver to handle a large glucose load. The arterial or venous blood gas commonly shows a respiratory alkalosis. Severe metabolic acidosis with elevated lactate occurs in patients with hepatic failure caused by mitochondrial injury. Measurements of serum lactate concentration may be useful in identifying the cause of acidosis in a patient with suspected toxic liver injury.^{103,108,144,159}

Computed tomography and magnetic resonance imaging scans are useful tests for evaluation of parenchymal disease of the liver. An ultrasound examination reliably demonstrates dilation of the extrahepatic bile ducts. Liver biopsy may be helpful but is not specifically diagnostic of xenobiotic-induced hepatic injury.

MANAGEMENT

In many patients, toxic liver injury resolves with simple withdrawal of the offending xenobiotic. In patients with severe injury, significant improvement in survival is associated with good supportive care in an intensive care environment.⁸⁷ Transplantation may be lifesaving for critically ill patients with acute liver failure. Early referral to a transplant center for patients with evidence of severe or rapidly progressive toxic injury is indicated.^{45,102} For discussion of indications for the use of N-acetylcysteine and discussion of indications for transplantation ([Antidotes in Depth: A3](#)).

SUMMARY

The primary role of the liver in the biotransformation of xenobiotics results in an increased risk of hepatotoxicity. Xenobiotic-induced liver injury can be dose-dependent and predictable or idiosyncratic and unpredictable.

- Predictability is evolving with the science of genome analysis. Injury that is apparently idiosyncratic is affected by host characteristics that include genetic makeup, concomitant or previous exposure to xenobiotics, and the underlying condition of the liver. The ability to predict this susceptibility is increasing.
- The pathological spectrum of liver injury includes combinations of hepatocellular necrosis, hepatitis, cholestasis, steatosis, apoptosis, and fibrosis.
- Mechanisms of hepatic injury include cell-mediated immune mechanisms that result in inflammation and fibrosis; antibody-mediated immune mechanisms that attack various hepatocyte targets including critical cellular enzymes; lipid

peroxidation initiated by free radicals; and mitochondrial injury.

24 NEUROLOGIC PRINCIPLES

Rama B. Rao

INTRODUCTION

The central nervous system (CNS) coordinates responses to the fluctuating metabolic requirements of the body and modulates behavior, memory, and higher levels of thinking. These functions require a diversity of cells: astrocytes, neurons, ependymal cells, and vascular endothelial cells. Disruption or death of any one cell type can cause critical changes in the function or viability of another. This cellular interdependence, along with the high metabolic demands of the CNS, makes neurons especially vulnerable to injury from both endogenous neurotoxins and xenobiotics. Endogenous neurotoxins, such as the metals iron, copper, and manganese, are substances that may be critical to CNS function but are harmful when their penetration into the CNS is poorly controlled.

The understanding of the normal chemical and molecular functions of the CNS is limited at best. Interestingly, cellular mechanisms have sometimes been revealed by investigating xenobiotic-induced neuronal injuries.^{38,68} For example, the pathophysiology of Parkinson disease, which affects movement and motor tone, was elucidated by the inadvertent exposure of individuals to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). The mechanisms of axonal transport were elucidated by investigations of the effects of acrylamide exposures in human and animal models.⁵⁸ The neurodegenerative changes of amyotrophic lateral sclerosis have a promising xenobiotic model in β -methylamino-L-alanine (BMAA), a neurotoxin found in the cyanobacteria associated with cycad plants ingested by the Chamorro people of Guam (Chap. 14).

There are few minimally invasive methods available to investigate xenobiotic-induced CNS injury. Biomarkers are usually nonspecific and not readily available. Xenobiotic concentrations of blood and urine rarely reflect tissue concentrations of the CNS.⁶⁰ Cerebrospinal fluid (CSF) may be useful in excluding CNS injury from infection, hemorrhage and inflammatory processes, but is, with few exceptions, poorly reflective of the etiology of neuronal injuries.⁹⁰ Similarly, electroencephalograms and electromyelograms are useful in only a few types of xenobiotic exposures, and neuroimaging, while progressively evolving,⁵⁴ is a poor substitute for neuroanatomical evaluations that are usually available only on autopsy. Much of the current study to elucidate the mechanisms of CNS injury uses animal models, cultured astrocytes, and other tissue, or postmortem investigations. Less commonly, occupational evaluations, such as the enzyme activity of cholinesterases in pesticide exposed workers, are used.

This chapter reviews some basic anatomic and physiologic principles of the nervous system and the common mechanisms by which xenobiotics exploit the functional and protective components of the CNS with a few relevant examples. The multiple factors determining the clinical expression of neurotoxicity are reviewed.

CELLS OF THE NERVOUS SYSTEM: AN OVERVIEW

Neurons

Neurons are the major pathway of cellular communication in the CNS. Having one of the highest metabolic rates in the body, these cells are especially sensitive to changes in the microenvironment and are dependent on astrocytes, choroidal epithelium, and capillary endothelium to confer protection and deliver glucose and other sources of energy.

Although each neuron is capable of receiving information through different neurotransmitters and receptor subtypes at the dendrite, neurons typically produce and release a single type of neurotransmitter at the axonal terminal. This specificity allows for cellular classification of neurons based on the neurotransmitter released, for example, serotonergic, cholinergic, and dopaminergic neurons (Chap. 14). Other substances such as adenosine may be produced and released that are less specific to the neuron type.

The anatomic structure of neurons facilitates their function. Dendrites located on the cell body are lined with receptors that bind neurotransmitters and affect cellular changes via several mechanisms. The soma, or cell body, is responsible for coordination and production of multiple proteins required to carry out normal physiological functions. This synthesis occurs at a rate several times greater than the liver or kidney. These proteins, organelles, and substrates must then be transported across long distances to the terminal axon. This energy-dependent function is supported by a cytoskeleton comprised of neurofilaments, microfilaments, microtubules, and complex transport proteins. Fast anterograde transport of membrane-bound organelles occurs through kinesin, a transport protein, at a rate of 200 to 400 mm/d. Channel proteins,

synaptic vesicles, mitochondria, $\text{Na}^+\text{-K}^+\text{-ATPase}$, glycolipids, and other substances are transported by kinesin. Slow anterograde transport also occurs at a substantially slower rate (0.5–4 mm/d). The retrograde transport protein, dynein, is produced in the soma and delivered to the nerve terminal for the movement of larger vesicles and reusable proteins back to the cell body.

In the CNS, groups of neurons are organized into complex functional pathways, with a single class of neuron regulating different functions and clinical effects depending on the brain region. As an example, dopaminergic neurons regulate cravings, movement, and resting muscle tone, each of which is determined not only by dopaminergic neurons and receptor subtype, but the location in the cortex or basal ganglia ([Chap. 14](#)).

Neurons must be able to respond to changes in the local environment and alter the expression of different receptors in response to signaling from neurotrophic factors, variations in metabolic requirements, and xenobiotic interactions. This “neuroplasticity” accounts for the diversity of clinical responses to xenobiotics that induce tolerance such as ethanol ([Chap. 15](#)).

Glial Cells

Glial cells are comprised of astrocytes, oligodendrocytes, Schwann cells, and microglia. These cells serve to support the neurons both structurally and functionally.

Astrocytes comprise between 25% and 50% of the brain volume.^{1,3,4,11} In addition to the anatomic contribution to the blood–brain barrier (BBB), astrocytes play a critical role in maintaining neuronal function.^{1,2,93} They contribute to three major areas: homeostasis of the extraneuronal environment, provision of energy substrates, and limitation of oxidative stress. In addition, astrocytes contribute to the “plasticity” of cells and receptor expression in the CNS (see later discussion).

In order for cells of all types to function in the CNS, membrane potentials must be adequately maintained. Astrocytes contribute to this by closely regulating the extracellular pH, water, and, like brain capillaries, the extracellular potassium concentration. Metallothioneins, which control the entry of metals necessary for CNS function, are produced by astrocytes.^{28,93} Astrocytes also release energy substrates such as lactate, citrate, alanine, glutathione, and α -ketoglutarate for utilization by neurons.¹¹

Astrocytes metabolize glutamate, the main excitatory amino acid (EAA) neurotransmitter in the CNS, as well as ammonia. These cells also produce superoxide dismutase and glutathione peroxidase to reduce free radical propagation. Glutathione, the major antioxidant for the brain, is predominantly located in the astrocytes. It can be released into the extracellular space or cleaved for neuronal uptake and intracellular reformulation.¹¹

Through the release of complex trophic factors, astrocytes control the expression of endothelial transporters of the BBB and the production of tight junctions in both the blood–CSF barrier and BBB. Angiogenesis is similarly astrocyte regulated, as is detection of neuronal injury, immune mediation, and neurotransmitter production. The growth of neurites, the branches of neuronal cell bodies that eventually become dendrites or axons, is similarly modulated by astrocytes.

Oligodendrocytes are a type of glial cell that provide anatomical support, protective insulation, and facilitate rapid neuronal depolarization by the production of myelin. Myelin is the primary constituent of white matter in the CNS. The production of myelin in the peripheral nervous system (PNS) is performed by the Schwann cells. Although oligodendrocytes support several axons, each Schwann cell is anatomically dedicated to a single axon.

Finally, microglial cells modulate immune response, inflammation, and tissue repair from a variety of CNS injuries. Like neurons, microglia are dependent on signaling from astrocytes.

MECHANISMS OF NEUROPROTECTION

The nervous system has multiple protective mechanisms. Xenobiotics are prevented from accessing the CNS by the blood–brain and blood–CSF barriers. For xenobiotics that enter the CNS, there are multiple cellular specializations to limit oxidant stress as reviewed below.

Blood–Brain Barrier

The BBB confers an anatomic and enzymatic barrier to xenobiotic entry into the CNS. Brain capillaries are surrounded by the foot processes of adjacent astrocytes. The potential spaces between endothelial cells are limited by tight junctions, or zonulae occludentes, which are between 50 and 100 times tighter than those found on peripheral capillaries.^{1,2,4,52,63} This anatomic barrier prevents movement of substances between cells, also known as the paracellular aqueous pathway, due to osmotic and oncotic forces.^{1,2,4,52,63}

Transendothelial movement of critical substrates and, potentially, xenobiotics occurs through three major mechanisms: diffusion, transport proteins, and endocytosis.^{1,4} These routes allow carefully controlled entry of critical substrates and cofactors while limiting the potential for injury from either endogenous or exogenous neurotoxins.

Lipophilic substances may move directly across the luminal and abluminal endothelial membranes abutting the CNS. Other substances may enter the endothelium through bidirectional transport proteins on the luminal surface. These proteins may be specific, such as the glucose transporter 1 (GLUT1) protein for uptake of glucose, or less specific large neutral amino acid transporters that move amino acids and xenobiotics, such as baclofen, intracellularly. These transporters also line the abluminal surface of the endothelial cell for movement of substrates and xenobiotics into the CNS. The third line of entry for larger proteins is via endocytosis. This can be adsorptive, or mediated through specific receptors such as those for insulin or transferrin.^{1,3,4,52,63,93}

Endothelial cells have other protective properties, including intracellular enzymes, to metabolize xenobiotics and efflux proteins to transport certain xenobiotics back into the capillary lumen. These efflux proteins include energy-dependent P-glycoproteins that are ATP-binding cassette transporters and are sometimes referred to as multidrug-resistant (MDR) proteins (Chap. 9). Several hydrophobic xenobiotics are prevented from accumulating in the CNS through these transporters, including vinca alkaloids, digoxin, cyclosporine A, and protease inhibitors. Nonsedating antihistamines may have limited sedative properties due, in part, to efflux through P-glycoproteins.²⁵ Another type of saturable transporter, known as organic acid transport (OAT) protein, facilitates the efflux of hydrophilic xenobiotics such as valproic acid or baclofen. The expression of each of these transporters may be upregulated under certain conditions such as intermittent disruptions in the BBB from seizures. This expression upregulation is theorized to account for the resistance of anticonvulsant medications in patients with epilepsy. Comprehensive lists of xenobiotics that are substrates for these transporters are available elsewhere.^{2,52,53}

Blood–Cerebrospinal Fluid Barrier

The ventricles of the brain are lined by the epithelial cells of the choroid. These cells also have tight junctions but not as extensive as those of the BBB. They are, however, rich in glutathione peroxidase and other xenobiotic-metabolizing enzymes in concentrations approximating those of the liver. Similar to brain capillary cells, the choroid contains efflux transporters for organic anions and cations, as well as MDR efflux proteins (P-glycoproteins) to limit entry of xenobiotics into the CSF.^{1,4,52,93}

NEUROTOXIC PRINCIPLES

Excitotoxicity

Neuronal function is strictly dependent on aerobic metabolism. When energy expenditure exceeds production, cellular dysfunction and ultimately cell death, or apoptosis, results. The specific cascade of molecular events relating to this process is termed excitotoxicity.^{10,73}

The initial event is traced to an oxidant stress and excessive stimulation of N-methyl-D-aspartate (NMDA) receptors by glutamate, an EAA neurotransmitter. An influx of intracellular calcium changes membrane potentials across the cellular and mitochondrial membranes. The mitochondria become progressively more inefficient at ATP production and handling the resulting reactive oxygen species. As membrane damage is propagated, calcium further depolarizes the mitochondria, activating a permeability transition pore across the mitochondrial membrane. Gradients are further disrupted, precipitating more injury, energy failure, and ultimately cell death.

Excitotoxicity is considered a common mechanism of cell death due to xenobiotic, ischemic, traumatic, infectious, neoplastic, or neurodegenerative injury. It is the subject of study for many therapeutic interventions in CNS injury.

Determinants of Neurotoxicity

The clinical expression of neurotoxicity is related to many factors. These include the chemical properties of the xenobiotic, the dose and route of administration, xenobiotic interactions, and underlying patient characteristics including age, gender, and comorbid conditions.

Chemical Properties of Xenobiotics

One of the most important determinants of neurotoxicity is the ability of a xenobiotic to penetrate the BBB. Water-soluble molecules larger than M_r 200 to 400 (molecular weight ratio, or mass of a molecule relative to the mass of an atom) are unable to bypass the tight junctions.⁴ Xenobiotics with a high octanol/water partition coefficient are more likely to passively penetrate the capillary endothelium, and potentially the BBB, whereas those with a low partition coefficient may require energy-dependent facilitated transport.⁶³ Xenobiotics that are substrates for capillary endothelial efflux mechanisms will have limited penetration regardless of the coefficient.^{1,4,52,63}

Route of Administration

The route of xenobiotic administration may also be consequential. Although most xenobiotics gain access to the nervous system through the circulatory system, aerosolized solvent and heavy metals in industrial and occupational exposures gain CNS access through inhalation, traveling via olfactory and circulatory routes. Alternatively, some substances may move from the PNS via retrograde axonal transport to the CNS. Naturally occurring proteins such as tetanospasmin, as well as rabies, polio, and herpes virus may use this mechanism to access the PNS and CNS.^{13,16,47} The toxalbumins ricin and abrin as well as bismuth salts may also use this mechanism to a limited extent.^{85,91} This understanding may prove beneficial from a therapeutic perspective. For example, in one small experimental series of patients experiencing severe pain, doxorubicin was injected into the involved peripheral nerves. Therapeutically, a chemical ganglionectomy occurred through retrograde “suicide” transport of doxorubicin, which provided substantial relief for these patients.⁵⁰

Some xenobiotics may be delivered directly into the CSF (intrathecally), the consequences of which are variable (Special Considerations: SC3).

Xenobiotic Interactions

Coadministration of xenobiotics may precipitate neurotoxicity by several mechanisms.⁴⁵ Extraaxially (outside of the CNS), xenobiotic interactions that result in an increase of the blood concentration of one or both may overwhelm the protective mechanisms of the BBB.²⁰ Similar effects may occur in the PNS where elevated blood concentrations may enhance clinical effects resulting in peripheral neuropathies.⁹³

Xenobiotic interactions can be synergistic, acting on the same neuroreceptor. Benzodiazepines and ethanol, for example, both stimulate the γ -aminobutyric acid type A (GABA_A) receptor. The excessive neuroinhibition can result in deep coma and even respiratory depression when these xenobiotics are administered simultaneously.

In some circumstances, xenobiotic interactions result in excessive neurotransmitter availability.⁹ This neurotransmitter excess is demonstrated in patients with the serotonin toxicity, which results from the coadministration of a monoamine oxidase inhibitor and a serotonin reuptake inhibitor or other serotonergics as an example (Chap. 75).

Access to the CNS may be altered by one of the xenobiotics, allowing the other to bypass the BBB. For example, mannitol causes transient opening of the BBB; as a result, therapeutic use of mannitol is under investigation for the delivery of chemotherapeutics that might otherwise be unable to access the nervous system.⁵³ Similarly, some xenobiotics, such as verapamil, cyclosporine, and probenecid, are blockers of capillary endothelium efflux.^{4,93} These theoretically limit efflux of other substrates of P-glycoprotein or OAT. The clinical utility of employing such efflux blockers is under investigation as was done in a study in which primates received intrathecal methotrexate. The CSF clearance of methotrexate was reduced in animals administered intrathecal probenecid.^{12,76}

Patient Characteristics

Patient-specific variables may affect the ability of a xenobiotic to penetrate the BBB and/or the clinical effects of a given exposure. For example, age of the patient at the time of exposure is critical, especially in the fetus and neonates.⁷⁸ The structural and enzymatic development of the BBB is incomplete, and synaptogenesis, or formation of intercellular relationships, is especially sensitive to impaired protein synthesis or other excitotoxic events. This is demonstrated classically by maternal exposure to methylmercury. The mother may be minimally affected, but the developing fetus suffers profound neurological and developmental consequences (Chaps. 31 and 98).

In neonates, immature liver function may lead to the accumulation of circulating bilirubin. Due to incomplete formation of the BBB, the bilirubin may access the CNS and produce a form of encephalopathy known as kernicterus.

Elderly patients may also have increased susceptibility to neurotoxins as a result of relatively impaired circulation or age-related changes in mitochondrial function that predispose to excitotoxicity.⁸¹ Xenobiotic-induced parkinsonism, or the unmasking of subclinical idiopathic Parkinson disease, may occur more readily than in younger patients. Animal models also suggest age-related sensitivity with one study noting increased manganese toxicity with advanced age.³⁶

Gender may be contributory to the expression of xenobiotic-induced neurological injury. In animal models, the presence of estrogen-related and progesterone-related compounds may be neuroprotective for some xenobiotic injuries.^{64,71} In humans, women are more susceptible to some movement disorders such as xenobiotic-induced parkinsonism and tardive dyskinesia, whereas dystonias and bruxism are more prevalent in young men.⁷⁴ The etiologies of these gender-related differences are incompletely understood.

Neurologic Comorbidities

Conditions affecting the integrity of the BBB can affect CNS penetration of xenobiotics and endogenous neurotoxins. For example, glutamate concentrations are normally higher in the circulatory system than the CNS.⁵⁷ Patients with trauma, ischemia, or lupus vasculitis³ may experience neuropsychiatric disorders as a result of increased penetration of glutamate

or sensitivity to additional xenobiotics. Similarly, inflammation associated with meningitis and encephalitis causes openings in the BBB, which may be exploited therapeutically. Intravenous penicillin achieves a higher CSF concentration in animals with meningitis than in those without meningitis.⁷⁷

In some patients, previously undiagnosed diseases become evident on exposure to xenobiotics. This is especially true in patients with peripheral neuropathies. For example, patients being treated with therapeutic doses of vincristine suffered a severe polyneuropathy due to unmasking of a previously undiagnosed Charcot-Marie-Tooth disease.^{9,22} Similarly, patients with diabetes mellitus, the commonest cause of peripheral neuropathy, or human immunodeficiency virus disease may have exacerbation of symptoms in the presence of antiretrovirals.^{24,72} Patients with myasthenia gravis may have exacerbation of weakness with aminoglycoside administration, which can affect transmission at the neuromuscular junction (NMJ).⁹²

Chronic exposures to some neuroinhibitory xenobiotics such as ethanol may alter neuronal receptor expression and upregulate or increase the amount of receptors for EAAs. In addition to receptor augmentation, neurotransmitter concentrations of the excitatory neurotransmitters glutamate and aspartate are increased, as is homocysteine. These changes induce a tolerance to neuroinhibitory xenobiotics acting on the same receptor, and patients require escalating doses to achieve the same clinical effect. In such patients, cessation of ethanol intake results in a relative deficiency of exogenous inhibitory tone. The patient experiences neuroexcitability and the clinical syndrome of withdrawal^{17,18} (Chap. 15).

Adequate nutritional status is important for the maintenance of normal neurological function. The BBB may not be adequately maintained in patients with malnutrition. Deficiencies of metal cofactors such as manganese, copper, zinc, and iron can affect neurological function. In some cases, the deficiencies enhance absorption of other xenobiotics. For example, iron deficiency enhances lead and manganese absorption in the gastrointestinal tract, which can ultimately overwhelm neuroprotective mechanisms. Vitamins serve as enzymatic cofactors in modulating the production of glutamate, homocysteine, and other amino acids. Specific vitamin deficiencies can precipitate neurological syndromes such as Wernicke encephalopathy in thiamine-depleted patients (Antidotes in Depth: A24 and Chap. 47). The toxicity of xenobiotics may also be enhanced. For example, a relative pyridoxine deficiency in patients with acute isoniazid overdose may result in seizures as a result of a relative excess of EAAs (Antidotes in Depth: A14 and Chap. 58). Glucose is a critical energy substrate that can cause profound neurological impairment when delivery is inadequate (Antidotes in Depth: A12 and Chap. 53).

Interestingly, certain conditions such as temperature may affect the toxicity of xenobiotics. For example, cooling may limit the impedance of acetylcholine neurotransmission caused by botulinum toxin.⁴¹

Extraaxial Organ Dysfunction

Kidney failure may impair metabolism or elimination of xenobiotics or endogenous neurotoxins such as urea, rendering it more available to the CNS. Hyperglycemia in patients with diabetes mellitus may also increase formation of CNS reactive oxygen species. Similarly, patients with liver failure may have elevations in CNS manganese resulting in Parkinsonism.^{51,79}

Hepatic encephalopathy illustrates the concept of excitotoxicity from endogenous neurotoxins. Hyperammonemia increases oxidative stress and free radical formation in astrocytes. Ammonia potentially decreases critical metabolic enzymes such as catalases, superoxide dismutase, and glutathione peroxidase. Nitric oxide (NO) production is increased due to elevations in NO synthetase. Under these conditions, astrocytes upregulate the expression of the peripheral benzodiazepine receptor (PBR) on the outer mitochondrial membrane. The PBR modulates the production of neurosteroids and, in turn, the GABA_A receptor. Continued CNS exposure to ammonia and other endogenous solutes propagates this oxidative and nitrosative stress to the mitochondrial membrane, potentially opening the mitochondrial permeability transition pore. Osmotic swelling of the mitochondrial membrane followed by excitotoxicity results in cerebral edema and hepatic encephalopathy.^{64–66}

SPECIFIC MECHANISMS OF NEUROTOXICTY

Alteration of Endogenous Neurotransmission

Xenobiotics can induce neurotoxicity by triggering changes in neurotransmission in either the CNS or PNS. In some cases xenobiotics enhance neurotransmission through a specific receptor subtype. This enhanced transmission can occur through inhibition of presynaptic metabolism (monoamine oxidase inhibitors), stimulation of neurotransmitter release (amphetamines), impairment of neurotransmitter reuptake (cocaine), or inhibition of synaptic degradation (acetylcholinesterase inhibitors).

Alternatively, synaptic neurotransmission may be impaired.⁸⁰ Xenobiotics may inhibit the presynaptic release of neurotransmitters (botulinum toxin), block receptors (antimuscarinics), or alter membrane potentials at the postsynaptic membrane (tetrodotoxin).^{32,33} Patients may present with a clinical syndrome of toxicity associated with altered neurotransmission of the specific receptor (Chap. 3).

Direct Receptor Interaction

Some xenobiotics are able to directly stimulate receptors. Both kainate and α -amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) are subclasses of the glutamate receptor, which are targeted by some naturally occurring xenobiotics.⁴² An example is β -N-oxalylamino-L-alanine (BOAA) found in the grass pea, *Lathyrus sativus*. BOAA stimulates the AMPA receptor and inhibits specific mitochondrial enzymes resulting in the spastic paraparesis of lathyrism.⁶⁹ Domoic acid stimulates the kainate receptor and causes the neuroexcitation associated with neurotoxic shellfish poisoning (Chap. 44). Direct inhibition is also possible, as exemplified by phencyclidine, an NMDA receptor antagonist.

Enzyme and Transporter Exploitation

The classic example of xenobiotics that exploit endogenous enzymes and or transporters is MPTP.³⁸ Once MPTP crosses the BBB, it is converted by monoamine oxidase to the neurotoxic compound 1-methyl-4-phenylpyridine (MPP⁺) in astrocytes. MPP⁺ is taken up by dopamine transporters into the neurons of the substantia nigra pars compacta. MPP⁺ inhibits complex I of the mitochondrial electron transport chain resulting in dopaminergic excitotoxicity and the clinical syndrome similar to Parkinson disease (Disorders of Movement and Tone, below, and Chap. 38).

Altered Conduction along Membranes:Demyelinating Neurotoxins

Aside from xenobiotics that affect neurotransmission at the postsynaptic membrane, some affect the production or maintenance of myelin by oligodendrocytes and Schwann cells.^{23,34,37,48} In the CNS these are often associated with white matter abnormalities and a leukoencephalopathy.³⁴ Xenobiotics such as hexachlorophene, arsenic, inhibitors of tumor necrosis factor α , neural tissue-derived rabies vaccine, and the act of “chasing the dragon” or inhaling volatilized heroin are associated with a demyelinating neurotoxicity.²³ In the PNS, nitrous oxide, suramin, and tacrolimus are associated with peripheral demyelination.⁴⁶

Inhibition of Intracellular Functions

Some xenobiotics are nonspecific inhibitors of cellular function.²⁹ For example, the neurotoxicity of carbon monoxide (CO) or cyanide that may appear as a diffuse impairment of neuropsychiatric dysfunction or, depending on the dose and specific vulnerabilities of an exposed patient, be more focal. Patients surviving acute CO exposure may experience delayed neurological sequelae that may include a diffuse impairment of neuropsychiatric function, or more focally, present with a xenobiotic-induced Parkinson syndrome (see later and Chap. 125).

Antineoplastics can affect the production of critical proteins required for cellular maintenance. These can be very specific such as the ability of vincristine to impair cytoskeletal transport in the peripheral nervous system (Chap. 36).

CLINICALLY RELEVANT XENOBIOTIC-MEDIATED CONDITIONS

Alterations in Consciousness

The toxicological differential diagnosis of xenobiotics that induce alterations in mental status or consciousness is expansive. These xenobiotics can be broadly divided into those that produce some form of neuroexcitation and those that produce neuroinhibition. Although some xenobiotics such as phencyclidine have elements of both depending on dose, this categorization facilitates a general clinical understanding of neurotoxic alterations in mental status.

Xenobiotics resulting in neuroexcitation enhance neurotransmission of EAAs, or diminish inhibitory input from GABAergic neurons. The clinical presentation of the patient may vary; some patients may be alert and confused, or suffering from an agitated delirium, hallucinations, or a seizure.

Neuroinhibitory xenobiotics typically enhance GABA-mediated neurotransmission. These patients may be somnolent or in deep coma. Benzodiazepines hyperpolarize cells by increasing inward movement of Cl⁻ ions through the chloride channel of the GABA_A receptor. This hyperpolarization limits subsequent neurotransmission (Chap. 14). Less commonly, neuroinhibition is a result of diminution of EAA. Patients presenting the day after bingeing on cocaine may be sleepy but arousable and oriented in what is termed cocaine “washout,” theoretically related to depletion of EAA and dopamine. Xenobiotics that cause diffuse cortical dysfunction through impairment in the delivery or utilization of oxygen or glucose can also present with depressed or altered consciousness.

Clinical evaluation of patients with altered consciousness includes obtaining complete history, including medications, comorbid conditions, occupation, and suicidal intent when relevant or available. Patients should have a complete physical examination, with particular attention paid to vital sign abnormalities or findings that may indicate a toxic syndrome. Assessment and correction of hypoxia or hypoglycemia should be performed. An electrocardiogram may be useful in some circumstances (Chap. 16).

Xenobiotic-Induced Seizures

Seizures are the most extreme form of neuroexcitation. As with alterations of consciousness, this may be due to enhanced EAA neurotransmission (domoic acid, sympathomimetics) or inhibition of GABAergic tone (isoniazid). Unlike in traumatic or idiopathic seizure disorders with an identifiable seizure focus, the initiation and propagation of xenobiotic-induced seizures is diffuse. It is for this reason that most non-sedative-hypnotic anticonvulsants such as phenytoin are unlikely to be effective in terminating xenobiotic-induced seizures.

Seizures may be idiopathic as described with tramadol and bupropion, or they may be concentration-dependent events as described with theophylline and isoniazid toxicity. Alternatively, seizures may be a result of withdrawal from GABAergic substances.

Status epilepticus is variably defined but involves two or more seizures without a lucid interval, or continuous seizure activity for greater than 5 minutes.⁵⁹ True xenobiotic-induced status epilepticus is rare. Cicutoxin, the toxin in water hemlock, *Cicuta maculata*, is a potent inhibitor of GABA_A neurotransmission and may cause status epilepticus.

Theophylline toxicity precipitates seizures and status epilepticus through a different mechanism. Normally, endogenous termination of seizures is mediated through presynaptic release of adenosine during the release of the primary neurotransmitter at the terminal axon. Adenosine functions as a feedback inhibitor of the presynaptic neuron, disrupting propagation of excitatory neurotransmission. Theophylline is an adenosine antagonist. Adenosine administration is not a useful therapy for theophylline-induced seizures as adenosine is unable to cross the BBB. Generally high-dose sedative-hypnotics, affecting GABA_A receptors, are required for seizure control.

Some clinical conditions appear to be centrally mediated tonic-clonic movements but are due to glycine inhibition in the spinal cord. Glycine is the major inhibitory neurotransmitter of motor neurons of the spinal cord. Under normal conditions, glycine contributes to termination of reflex arcs. Glycine inhibition results in myoclonus, hyperreflexia, and opisthotonos, often without alteration in consciousness. Presynaptic glycine release inhibition is caused by tetanospasmin, the major neurotoxin from *Clostridium tetani*. Postsynaptic glycine inhibition is caused by strychnine, the toxin in *Strychnos nux-vomica*. Patients with exposures to tetanospasmin or strychnine are often treated in quiet environments where the stimuli to initiate hyperreflexia are minimized ([Chap. 117](#) and [Table 24-1](#)).

TABLE 24-1. Xenobiotics That Commonly Induce Seizures

<i>Concentration Related</i>	<i>Idiosyncratic</i>	<i>Withdrawal Related</i>	<i>Tonic-Clonic Seizurelike</i>
Antihistamines	Bupropion ^a	Baclofen	Strychnine
Baclofen	Carbamazepine	Barbiturates	Tetanospasmin
Camphor ^a	Ergotamines	Benzodiazepines	
Carbon monoxide	GHB	Ethanol

Tetramethylenedisulfotetramine (TETS) ^a			
Thallium			
Theophylline ^a			
Zinc phosphide			

^aHigh concentrations may result in status epilepticus.

CNS = central nervous system; GHB = γ -hydroxybutyric acid.

Xenobiotic-Induced Mood Disorders

Certain xenobiotics are inconsistently associated with alterations in mood.^{5,19} What predisposes individuals to xenobiotic-induced mood alterations is unclear. In some circumstances, patients with previously undiagnosed bipolar disorder are given a xenobiotic that unmasks their disease. Interestingly antibiotic-induced mania is found in some patients without a previous psychiatric history. The symptoms of mania are usually evident within the first week of therapy and, unlike the mania of purely psychiatric origin, readily abate within 48 to 72 hours of the last antibiotic dose. Some patients with clarithromycin-induced mania have documented recurrence on rechallenge.⁵ In general, xenobiotic-induced manias are idiopathic and very rare. More common are either psychosis from chronic CNS stimulant use or depression from ethanol or the xenobiotics listed in [Table 24–2](#).

TABLE 24–2. Xenobiotics Commonly Inducing Mood and Neuropsychiatric Disorders

<i>Mania</i>	<i>Depression</i>	<i>Psychosis</i>
Acyclovir	β-Adrenergic antagonists	Amantadine
Amantadine	Amiodarone	Corticosteroids
Caffeine	Interferon	CNS stimulants
Chloroquine	Isotretinoin acid	
Clarithromycin	Ribavirin

Pseudoephedrine		
Quetiapine		
St. John's wort		
Testosterone		
Tramadol		

CNS = central nervous system.

Disorders of Movement and Tone

Central Nervous System–Mediated Disorders. Most movement disorders, including akathisia, bradykinesia, tics, chorea, and dystonias, are mediated by the complex dopaminergic pathways of the basal ganglia. Different dopamine receptor subtypes are modulated by serotonergic, GABAergic, glutaminergic, and cholinergic neurons ([Chap. 14](#)).

Chorea occurs in some cases of carbamazepine overdose, therapeutic oral contraceptive use,³¹ and after cocaine use when the stimulant effects have subsided.⁷⁴

Dopamine receptor antagonists can precipitate acute dystonic reactions. The D₂ receptor antagonists, in conjunction with alterations in muscarinic cholinergic tone, are usually implicated. Animal models suggest possible mediation through σ receptors, the craniofacial distribution of which corresponds to the common clinical manifestations of acute dystonias.⁴⁹

Diffusely increased motor tone may occur with glycine antagonists such as tetanospasmin and strychnine, and in adrenergic states such as acute toxicity with CNS stimulants, or withdrawal from sedative-hypnotics. The rare complication of bone fractures associated with severe muscle spasm and myoclonus is reported with chronic bismuth toxicity and inadvertent intrathecal administration of hyperosmolar contrast dye ([Chap. 90](#) and Special Considerations: SC3).

Other centrally mediated disorders of tone include serotonin toxicity and neuroleptic malignant syndrome (NMS). Both of these potentially life-threatening disorders consist of altered consciousness, hyperthermia, rigidity, and autonomic instability. NMS may occur in patients taking dopamine receptor antagonists such as antipsychotics or in those with idiopathic Parkinson disease who abruptly stop their dopamine agonist therapy. Dopamine receptor agonists such as bromocriptine or restoration of antiparkinson medications are used therapeutically in these circumstances ([Chap. 70](#)). The diagnosis and management of serotonin toxicity is reviewed in [Chap. 75](#).

Parkinsonism. Xenobiotic-induced parkinsonism is a syndrome of unstable posture, rigidity, gait disturbance, loss of facial expression, hypokinesia, and variable presence of tremor.⁷ The common neuroanatomic target involves the dopaminergic neurons of the basal ganglia, specifically the substantia nigra.^{26,86} In some circumstances, the toxicity is

transient and the mechanism inadequately understood.

Some xenobiotics such as carbon monoxide and heroin produce tissue hypoxia and ischemia in the basal ganglia that occasionally results in xenobiotic-induced Parkinson syndrome.

Other xenobiotics such as MPTP, carbon disulfide, manganese, and the endogenous neurotoxin copper in patients with Wilson disease produce predictable mitochondrial impairment of the basal ganglia neurons. Viscose rayon workers exposed to carbon disulfide may present with a Parkinson syndrome refractory to L-dopa administration^{43,44} (see Enzyme and Transporter Exploitation earlier).

Manganese is a critical substrate for production and metabolism of several neurotransmitters including glutamate. Excessive manganese interferes with normal uptake of glutamate and is critical to the function of superoxide dismutase and glutamine synthetase.^{30,35} In patients with liver failure who accumulate manganese from occupational exposure, reversal or treatment of liver disease may result in resolution of parkinsonism.^{36,79}

A recent review of patients who intravenously injected the illicit methcathinone described a Parkinson syndrome thought to be secondary to contamination with manganese from a precursor, potassium permanganate, which is used in methcathinone production. Unlike patients with idiopathic parkinsonism, these patients did not suffer from a resting tremor, and they had a specific gait abnormality in which they walked on the balls of their feet.⁸⁴ Like those with occupational manganese exposures and normal liver function, these patients did not respond to L-dopa (Table 24–3).

TABLE 24–3. Xenobiotics Commonly Inducing Parkinsonism

Reversible ^a	Irreversible
Amlodipine	Carbon disulfide
Antipsychotics	Carbon monoxide
Cyclosporine	Copper
Calcium channel blockers	Cyanide
Chemotherapeutics	Heroin
Dopaminergic agonists (withdrawal)	Manganese
Kava kava	MPTP
Progesterone	
Valproate	
Trazodone	

^aMay improve with removal of xenobiotic, sometimes requiring persistent administration of dopaminergic therapy.

MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

Tremors. Tremors may be observed with adrenergic excess, with specific xenobiotics such as lithium, or as a result of sedative–hypnotic withdrawal. These are well reviewed elsewhere.⁶²

The Neuromuscular Junction. Flaccid paralysis usually occurs as a result of impaired transmission at the NMJ^{14,15,80} or from xenobiotics causing demyelination.⁵⁵ Mechanisms of NMJ transmission impairment include impeded propagation of the action potential on the terminal neuron, impaired release of acetylcholine, depression of motor end-plate potential with failure of depolarization, and impedance of myofibril excitation^{55,80} (Chap. 69).

Rarely xenobiotics can enhance transmission at the NMJ. Latrotoxin, the toxic compound in the black widow spider (*Latrodectus* spp) venom causes enhanced release of acetylcholine at the NMJ with severe, painful muscle contractions. Some types of scorpion venom act similarly (Chap. 118).

NEUROPATHIES AND MYOPATHIES

Cranial Nerves

Xenobiotics are a relatively rare cause of cranial nerve impairment. Some neuropathies are a result of direct delivery of the xenobiotic to the affected cranial nerve. For example, some patients may have optic nerve impairment from intraorbital installation of silicone oil⁶ or inadvertent deep space injection of a local anesthetic during dental anesthesia with a resultant abducens palsy.⁶¹ In some cases, a xenobiotic, methanol is converted into a toxic substance such as formic acid in the retina.

The neuromuscular junction of the cranial nerves is sensitive to disruptions in neurotransmission. When xenobiotics affect the oculomotor nerves (cranial nerves (CN) III, IV, VI), patients may describe diplopia or have gaze palsies on

examination. Botulinum toxin, diethylene glycol toxicity, elapid snake venom, and the cranial neuropathy associated with the organic phosphorus insecticide-induced intermediate syndrome are some examples.

Absence of critical substrates such as glucose or thiamine can result in ophthalmoplegia. In most cases, however, the mechanisms underlying the cranial neuropathy are poorly understood, such as is the case with antineoplastics. Similarly, some patients who survive ethylene glycol poisoning experience transient ophthalmoplegia days after the initial exposure^{56,83} (Table 24-4 and Chap. 25).

TABLE 24-4. Cranial Neuropathies

Cranial Nerve	Sign	Symptom	Xenobiotic
I		Failure to detect odor	Hydrogen sulfide; olfactory fatigue
II	Pupil unresponsive to light	Blindness	Amiodarone, ammonia, cisplatin, cloquinal, deferioxamine, DEG, dimethyl mercury, holocyclotoxin, interferon α , methadone, methotrexate, methyl iodide, oxaliplatin, quinine, solvents
III	In paralysis: ptosis, pupil unresponsive to light In excess: miosis	Photophobia Dim vision Muscarnic cholinergics	Amiodarone, antimuscarinics, botulinum toxin, DEG, holocyclotoxin, hypoglycemics, interferon α , methyl iodide, thallium, venoms (Eupidae, scorpion)
IV	Paralysis of the superior oblique muscle of eye with weakness of downward gaze, slight upward gaze of affected eye	Vertical and torsional diplopia that worsens on adduction and may improve with tilt of head	Barbiturates, botulinum toxin, DEG, holocyclotoxin, thallium, venoms
V	Diminished facial sensation, weakness in chewing and swallowing Excessive contraction: trismus	Paresthesia face, weakness in chewing Difficulty opening mouth/jaw	Botulinum toxin, ethylene glycol, holocyclotoxin, oxaliplatin, vincristine Tetanus toxin and strychnine ^b
VI	Failure to abduct eye on lateral gaze	Diplopia	Botulinum toxin, DEG, holocyclotoxin, intrathecal water-soluble contrast agents, lithium, local anesthetics, MDMA, nitroglycerin, ornithine-ketoacid transaminase, oxaliplatin, thallium, thiamine deficiency, venoms (elapid), vitamin A
VII ^a	Weakness of facial muscles, impaired expression	Facial droop, impaired taste	Botulinum toxin, DEG, ethylene glycol, holocyclotoxin
VIII ^a	Impaired hearing on auditory testing, nystagmus	Alterations in hearing, potential alterations in balance	Cisplatin, DEG, ethylene glycol, oxalosis, quinine, salicylates, solvents
IX	Impaired gag reflex	Impaired taste	Botulinum toxin, cholinergic compounds, ethylene glycol, stibarsite ^c
X ^d	Decreased gag reflex when paralyzed May be enhanced with cholinergic or impaired with anticholinergic; autonomic instability, altered bowel sounds	Choking, change in voice	Botulinum toxin, cholinergic compounds, ethylene glycol, stibarsite ^c
XI	Weakness shoulder shrug	Weakness neck/shoulders	Botulinum toxin, cholinergic compounds
XII	Impaired speech, tongue deviation	Dysarthria	Botulinum toxin, cholinergic compounds

^aSee also Chap. 26. ^bTetanus causes indirect effects on muscular muscles; see section on xenobiotic-induced seizures in Chap. 112. ^cWeakness of cranial nerves IX–XII is often referred to as bulbar palsy and can be seen in the intermediate syndrome after acute organic phosphorus compound poisoning. This syndrome is often accompanied by paralysis of extraocular muscles (Chap. 113). ^dSee Chap. 3.

DEG = diethylene glycol; MDMA = methylenedioxymethamphetamine.

Peripheral Nerves

Complaints of pain, paresthesias, numbness, or weakness of extremities are clinically termed neuropathies. The mechanisms of evolution are variable. Common to most xenobiotic-induced neuropathies is early symmetrical involvement of the lower extremities. This may be due in part to the patient's rapid recognition of impairment during an attempt to ambulate. Additionally, the axons serving the lower extremities are longer. Maintenance and transportation of substrates is more energy dependent and sensitive to xenobiotic-induced disruptions.

In some cases, the anatomic structure of the nerve is maintained, but the xenobiotic affects neurotransmission. This may be due to direct impairment of specific enzymes at the NMJ, such as cholinesterase inhibitors.²⁷ Tri-ortho-cresyl phosphate (TOCP) is an inhibitor of neuropathic target esterase. Contamination of food and the beverage Ginger Jake with TOCP resulted in irreversible lower extremity paralysis in several epidemic exposures.^{70,88} Indirectly, the extracellular environment may be altered as in the case of hypermagnesemia, or hypokalemia which can be induced by multiple xenobiotics ([Chap. 19](#)). Ciguatoxin, a sodium channel opener, affects neurotransmission, causing paresthesias and the unusual symptom of temperature reversal in which the perception of temperature is opposite to the stimulus.

Xenobiotics such as amiodarone and tacrolimus induce peripheral demyelination. Patients present with weakness and flaccidity. Nitrous oxide impairs the production of S-adenosyl methionine essential to the production of myelin and is additive to the nitrous oxide disruptions of vitamin B₁₂, which further impair axonal function.⁸⁹

Other xenobiotics affect the structure or intracellular function of the peripheral nerves. Those that induce death of the cell body are termed neuronopathies, and they may be clinically indistinguishable from those that affect the axon, or axonopathies.

Peripheral nerve cell death is usually linked to injury at the spinal cord as was described above by the doxorubicin injection of the peripheral nerves.⁵⁰ Pyridoxine overdose is another cause of neuronopathy. However, neuronopathies are an unusual mechanism of peripheral nerve toxicity.

Unlike neuronopathies, axonopathies are potentially reversible and are the most common mechanism of xenobiotic-induced peripheral neuropathy. Xenobiotic-induced axonal injuries to the peripheral nerves are usually diffuse and bilateral, with preservation of the proximal cell body. These often target the cytoskeleton and impair the capacity for the microtubule system to deliver functional substrates.^{21,40} Patients with occupational exposure to 2,5-hexanedione, a diketone metabolite of n-hexane present in certain glues, suffer from a sensorimotor axonopathy due to cross-linking of neurofilaments and impaired substrate transport.⁶⁷ Progressive neuropathy may occur long after the initial exposure. Vincristine similarly affects axonal transport. Acrylamide impairs fast anterograde and retrograde transport in animal models, suggesting effects on both kinesin and dynein. Nucleoside reverse transcriptase inhibitors cause peripheral neuropathy by decreasing the production of mitochondrial DNA.

Myopathies

Some patients experience local muscle damage as a result of direct injury from extravasation of tissue toxic substances or enzymatic degradation associated with crotalid snake envenomations.

Most xenobiotic-induced muscle injuries or myopathies are more diffuse.^{39,75,82,87} 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG Co-A) reductase inhibitors can cause myalgias, cramping, myositis, or rhabdomyolysis. The incidence appears to be higher in patients taking other medications that share the same liver metabolic enzymes. The mechanism underlying the myopathy may be related to impaired cholesterol synthesis in myocytes or diminished production of regulatory proteins such as ubiquinone and GTP-binding proteins required for mitochondrial function.

Another myopathy that presents predominantly with weakness is the acute quadriplegic myopathy of intensive care patients. This syndrome was originally described in ventilated patients with asthma who received glucocorticoids and nondepolarizing neuromuscular blockers, but is also reported in other critically ill patients⁸ ([Chap. 69](#)). The mechanisms underlying quadriplegic myopathy, eosinophilia myalgia syndrome, and toxic oil syndrome are poorly described. Xenobiotics associated with muscle injury can be found in [Table 24–5](#).

TABLE 24–5. Xenobiotics Associated with Muscle Toxicity

ε-Aminocaproic acid
Amiodarone
Chloroquine
Cimetidine
Clofibrate
Clostridium toxins
Cocaine
Colchine

Cyclosporine
Doxylamine
Ethanol
Ethchlorvynol
Glucocorticoids
Heroin
HMG-CoA reductase inhibitors
Hydroxychloroquine
Loxosceles spp venom
Niacin
Organic phosphorous compounds
D-Penicillamine
Phencyclidine
Procainamide
Propylthiouracil
Rifampin
Snake venoms
Succinylcholine
Sulfonamides
Syrup of ipecac
Toxic oil syndrome
Tricholoma equestre (mushroom)
L-Tryptophan
Vincristine
Zidovudine

SUMMARY

- With improved understanding of these neurotoxic principles, therapeutic medications can be better delivered to the CNS while limiting the entry of potentially toxic xenobiotics.
- Toxicological models for the investigation of neurodegenerative disorders can be further developed as can new and creative therapies for mood disorders, hepatic encephalopathy, and injuries from infections, trauma, and ischemia.
- Elucidation of neurotoxicologic principles shows promise for the treatment of many nervous system disorders.
- The chemical properties of the xenobiotic and the characteristics of the patient exposed are critical to the clinical expression of neurotoxicity.

25 OPHTHALMIC PRINCIPLES

Adhi Sharma

While it is arguable that the eyes are the mirror to the soul, it is certain that the eyes can reveal a great deal of information with regard to toxicology. In addition to exhibiting findings of systemic toxicity, they are also subject to the direct effects of xenobiotics and can serve as a portal of entry for systemic absorption. An understanding of ophthalmic principles will allow the clinician to make timely and more accurate diagnoses that can be sight-saving or lifesaving and is essential to efficient, organized patient care.

OPHTHALMIC EXAMINATION

As a matter of convention, the routine eye examination is performed in the following sequence: visual acuity, pupillary response, extraocular muscle function, funduscopy, and, when indicated, a slit-lamp examination. Examination of the pupillary size and response to light can help determine the presence of a toxic syndrome. For example, opioids and cholinergics may produce miosis, whereas anticholinergics and sympathomimetics may produce mydriasis. Assessment of the extraocular muscles can reveal xenobiotic-induced nystagmus or cranial nerve abnormalities. Funduscopy can reveal pink discs characteristic of poisoning by methanol or carbon monoxide. The slit-lamp examination allows for evaluation of toxic exposure to the lids, lacrimal systems, conjunctiva, sclera, cornea, and anterior chamber. However, before considering specific xenobiotic exposures in detail, it is important to review the anatomy and physiology of the visual pathways and how alteration of the normal physiology and anatomy correlate with clinical signs and symptoms.

OCULAR ANATOMY AND PHYSIOLOGY

The eye is a roughly spherical structure referred to as a globe. The globe is divided into anterior and posterior structures ([Fig. 25–1](#)). The most anterior structures are the cornea, conjunctiva, and sclera. Posterior to the cornea are the iris, the lens, and the ciliary body. The space between the cornea and the iris is the anterior chamber, and the space between the iris and the retina is the posterior chamber. The anterior chamber contains aqueous humor, which is produced by the ciliary processes; this fluid nourishes the cornea, iris, and lens. The iris, the ciliary processes, and the choroid compose the uvea. The posterior chamber is filled with a transparent gelatinous mass termed the vitreous humor. The vitreous humor is an important body fluid in forensic toxicology as it is less susceptible to postmortem redistribution ([Chaps. 7 and 34](#)). The fundus is the most posterior structure and includes the retina, retinal vessels, and the head of the optic nerve or disc.

FIGURE 25–1. The major xenobiotics that cause ophthalmic toxicity and their areas of ophthalmic injury.

Visual Acuity and Color Perception

Normal vision is dependent on light transmission through the globe reaching intact posterior neural elements. As such, appropriate light transmission requires a clear cornea, clear aqueous humor, proper pupil size, an unclouded lens, and clear vitreous. The posterior neural elements include the retina, optic nerve, and the optic cortex; in turn, all of these structures require intact blood circulation for proper function. Decreased acuity can result from abnormalities anywhere in the visual system that affect either light transmission or the neural elements.^{4,12,21} Corneal injury or edema may result in blurring of vision, characteristically described as “halos” around lights. Toxicologic causes of corneal abnormalities include direct exposure to chemicals, failure of corneal protective reflexes because of local anesthetic effects or a profoundly decreased level of consciousness, and incomplete eyelid closure during coma. Mydriasis (Table 25–1) may interfere with the pupillary constriction necessary for accommodation, thereby resulting in decreased acuity for near objects. Lens clouding or cataract formation causes blurred vision and decreased light perception, as does blood (hyphema), pus (hypopyon), or other deposits in the aqueous humor or vitreous humor (vitreous hemorrhage). Xenobiotic-induced lens abnormalities caused by chronic exposures are well described (Table 25–2)^{17,21,27} but are unimportant in the evaluation of an acute toxicologic emergency. Even if light reaches the retina without distortion, abnormal reception or transmission can result from ischemia or injury to any neural element from the retina to the optic cortex. Direct, acute, visual neurotoxic injury is rare and is caused almost exclusively by methanol or quinine. Indirect injury following xenobiotic-induced central nervous system (CNS) ischemia or hypoxia is far more common. Alterations in color perception generally result from abnormalities

in retinal or optic nerve function. Color-vision abnormalities are attributed to hundreds of xenobiotics, but unlike those caused by chronic xenobiotic exposure such abnormalities are rare and inconsistent features of acute toxicity.^{16,21}

TABLE 25–1. Ophthalmic Findings Caused by Acute Xenobiotic Exposures

Disconjugate gaze

Botulism

Elapid envenomation

Neuromuscular blockers

Paralytic shellfish poisoning

Secondary to decreased level of consciousness (many causes)

Tetrodotoxin

Thiamine deficiency

Funduscopy abnormalities

Carbon monoxide (red)

Cocaine (vasoconstriction)

^cReported, but extremely rare from this exposure. ^dMostly of historical interest; associated with patterns of use that are no longer common.

Pupil Size and Reactivity

Generally, pupils are round and symmetric with an average diameter of 3 to 4 mm under typical light conditions. Physiologic anisocoria (unequal pupils) is a normal variant and is defined as a difference in pupil size of 1 mm or less. However, in the absence of a history of physiologic anisocoria, any asymmetry in pupil size should be considered an abnormal finding. Pupils react directly and consensually to light intensity by either constricting or dilating. Constriction is also a component of the near reflex (accommodation) that occurs when the eye focuses on near objects. The iris controls pupil size through a balance of cholinergic innervation of the sphincter (constrictor) muscle by cranial nerve III and sympathetic innervation of the radial (dilator) muscle.¹²

Pupillary dilation (mydriasis) can result from increased sympathetic stimulation of the radial muscle by endogenous catecholamines, or from xenobiotics such as cocaine, amphetamines, and other sympathomimetics as well as ophthalmic instillation of sympathomimetics such as phenylephrine. Mydriasis can also result from inhibition of muscarinic cholinergic-mediated innervation of the sphincter secondary to systemic or ophthalmic exposure to anticholinergics ([Chap. 49](#)). Because pupillary constriction in response to light is a major determinant of normal pupil size, blindness from ocular, retinal, or optic nerve disorders also leads to mydriasis as exemplified by methanol and quinine toxicity. As such, the reactivity of mydriatic pupils to light varies with the etiology of the mydriasis.²¹ Although often difficult to appreciate, constriction to light can usually be elicited after sympathomimetic exposures because constrictor function is preserved, whereas this is often not the case when mydriasis results from anticholinergic excess since constrictor function is potentially antagonized. Light reactivity is absent in cases of complete blindness but may be preserved if there is some remaining light perception.

Miosis can result from increased cholinergic stimulation such as opioids, pilocarpine, and cholinesterase inhibitors, such as organic phosphorus compounds, or inhibition of sympathetic dilation caused by clonidine. Miosis was the most common finding in victims of the Tokyo subway sarin attack of 1995 and was used to distinguish between mild and moderate exposure.³³

There are conflicting reports regarding the pupillary reactions to many xenobiotics. Depending on the stage and severity of toxicity, the presence of coingestants or coexistent hypoxemia, and numerous other factors, many individual xenobiotics (eg, clonidine, nicotine, phencyclidine, and barbiturates) are reported to cause either mydriasis, miosis, or hippus, which is defined as a fluctuation between miosis and mydriasis.^{21,28} For some xenobiotics, the pupillary examination provides consistent information ([Table 25–1](#)), but many factors are involved and the significance of the pupil size and reactivity must always be considered in the context of the remainder of the patient evaluation.

Extraocular Movement, Diplopia, and Nystagmus

Maintenance of normal eye position and movement requires a coordinated function of a complex circuit involving bilateral frontal and occipital cortices, multiple brainstem nuclei, cranial nerves, and extraocular muscles.^{2,12} Because of the many elements necessary for normal function, abnormalities of eye movement can result from several causes and are extremely common.²¹ Probably the most common abnormality is reversible nystagmus or rhythmic oscillations of the globes ([Table 25–1](#)). Nystagmus is divided into two types: jerk nystagmus, which has a slow phase and a fast phase, and pendular nystagmus which has rhythmic oscillation. Either type can be torsional (rotary) or in a horizontal or vertical direction. Xenobiotic-induced nystagmus can take many forms but is most commonly jerk nystagmus, as opposed to pendular. The nystagmus may be evident at rest but is accentuated by visual pursuit and extreme lateral gaze. Although nystagmus with extreme lateral gaze is a normal finding, it extinguishes within 2 to 5 beats; if nystagmus persists, it is evidence of

underlying pathology. Vertical nystagmus in other settings is usually associated with a structural lesion of the CNS. However, xenobiotic-induced vertical nystagmus occurs with phencyclidine, ketamine, dextromethorphan, or phenytoin toxicity. Loss of conjugate gaze commonly results from CNS depression of any etiology, typically after sedative-hypnotic or ethanol poisoning. Except after extremely rare exposures to neurotoxins (Table 25–1), diplopia without a decreased level of consciousness should not be attributed to an acute toxicologic etiology. In addition to the transient effects of some xenobiotics, thallium, carbon disulfide, and carbon monoxide may cause sustained gaze disorders as a consequence of residual cranial nerve and CNS injury.²¹ Nystagmus and ophthalmoplegia caused by thiamine deficiency (Wernicke encephalopathy) usually improves after therapy, but the nystagmus may not completely resolve.⁴³

DIRECT OCULAR TOXINS

Caustics

The initial approach to all patients with ocular caustic exposures should be immediate decontamination by irrigating with copious amounts of fluids.^{9,44} Water, 0.9% sodium chloride solution, lactated Ringer solution, and balanced salt solution (BSS) are all appropriate choices. In theory, BSS is ideal, because it is both isotonic and buffered to physiologic pH. Lactated Ringer solution (pH 6–7.5) and 0.9% sodium chloride solution (pH 4.5–7) are also isotonic and therefore theoretically preferable to water.²² The use of an ocular anesthetic is usually required to perform irrigation properly. Irrigation is intended to accomplish at least four objectives: immediate dilution of the offending xenobiotic; removal of the xenobiotic; removal of any foreign body; and, in some cases, normalization of anterior chamber pH. Because delays of even seconds can dramatically affect outcome,²¹ there is no justification for waiting for any specific solution if water is the first available therapy. Irrigation must include the external and internal palpebral surfaces, as well as the cornea and bulbar conjunctiva and its recesses. Effective irrigation includes lid retraction and eversion or use of a scleral shell or other irrigating device. After irrigation, visual acuity testing, inspection of the eye, and slit-lamp examination should be performed. The immediacy with which an ophthalmologic consultation must be obtained will depend on the degree of injury.

Sulfur Mustard

This alkylating agent reacts with ocular tissues resulting in early and late toxic effects. Of note, there is a latency of 30 minutes to 8 hours, during which time victims are asymptomatic. Initial effects include pain, foreign body sensation (grittiness), lacrimation, photophobia, blepharospasm, corneal ulceration, and blindness.²⁴ Generally, injury is limited to the anterior chamber. More than 90% of exposed victims will experience late complications associated with conjunctival sensitivity to irritants with resultant recurrent blepharoconjunctivitis. Fewer than 1% of severely toxic victims will suffer delayed keratopathy, resulting in thinning, neovascularization, and epithelial defects of the cornea.²⁴

Management is directed at removal from the exposure and aggressive decontamination of the skin and eyes. Any of the irrigation solutions mentioned above will suffice. The goal is to provide irrigation as soon as possible; to this end, even tap water is an acceptable solution. Animal studies suggest that topical antiinflammatories are helpful; as such, a short course of ocular steroids may be beneficial.⁵ Steroid treatment should only be rendered in consultation with an ophthalmologist. Late complications are best managed by an ophthalmologist.

Exposure-Specific Irrigating Solutions

Despite theoretical concern, there is probably no toxic exposure for which standard aqueous solutions are contraindicated. Of greatest concern are xenobiotics such as white or yellow phosphorus, metallic sodium, metallic potassium, and calcium oxide (cement) that may react violently in the presence of water, leading to heat or mechanical injury, or resulting in the generation of sodium hydroxide, potassium hydroxide, and calcium hydroxide.²¹ Although not well studied, irrigation with large amounts of water probably dissipates the heat of the initial hydration reaction with conjunctival moisture more than it initiates a thermochemical reaction. In addition to removing the offending material, irrigation serves to dilute and remove the alkaline by-products formed by reaction with conjunctival water. Table 25–3 summarizes irrigation solutions for various xenobiotics.

TABLE 25–3. Irrigation Solutions for Various Xenobiotics

<i>Xenobiotic</i>	<i>Irrigation Solution</i>	<i>Duration of Irrigation^a</i>
Caustics (acids/alkalis)	NS, LR, BSS	1–2 hours
Hydrofluoric acid	NS	1–2 hours ^a
Phenol	NS, LR, BSS	15–20 minutes
Cyanoacrylate adhesives	Typically none needed	N/A
Capsaicin (pepper spray)	NS, LR, BSS	15–20 minutes

^aDuration of irrigation can also be determined by other endpoints, including symptoms or conjunctival pH. BSS = balanced saline solution (pH ~7.4); LR = lactated Ringer solution (pH 6.0–7.5); NS = 0.9% sodium chloride (pH ~5.5).

The use of special irrigating solutions for more uncommon exposures, including hydrofluoric acid and phenols, is also debated. Animal models of alkaline injury suggest irrigation with amphoteric or buffered solutions rapidly restores anterior chamber pH.³⁸ Some authors have gone further to conclude that 0.9% sodium chloride solution should be avoided as an irrigation solution.³⁵ Unfortunately, these were all ex vivo models, and the majority of the published human data have been case reports. Therefore, at this time these solutions are probably best suited for first aid treatment at worksite eyewash stations and are neither practical nor proven in the emergency department setting for prolonged irrigation.

Hydrofluoric Acid. For hydrofluoric acid exposures ([Chap. 107](#)), experimental irrigation with calcium salt solutions was too irritating to the eye, but isotonic magnesium chloride solutions appear effective and not irritating.^{29,30} From a practical standpoint, however, 0.9% sodium chloride solution remains readily available, well studied, and effective. In one animal model, it was suggested that irrigation beyond the initial liter yielded worse outcomes; however, this has not been demonstrated in humans.²⁹

Phenol. For dermal exposure, topical low-molecular-weight polyethylene glycol (PEG) solutions are effective for treatment of experimental skin exposure; for eyes, copious water irrigation appears to be as effective as PEG.⁷ There is, however, a report of superior efficacy of PEG-400 over water in treatment of actual phenol eye burns.²⁶ Although PEG-400 may be readily available at worksites where phenols are used, it is not a realistic option in the emergency department, and there should be no hesitation to use water, 0.9% sodium chloride solution, lactated Ringer solution, or BSS as lavage solutions.

Cyanoacrylate Adhesives. Ocular exposures to cyanoacrylate adhesives such as Dermabond and Krazy Glue occasionally result in rapid adherence between the upper and lower eyelids that may persist for days. Such occurrences may be associated with corneal abrasions¹³ but are otherwise relatively harmless. In fact, cyanoacrylate has been safely used for decades to treat corneal perforations.⁴⁶ Solvents such as acetone or ethanol, which are often effective treatment for dermal-to-dermal adhesions caused by cyanoacrylates, should never be used in or around the eyes because they can result in a severe keratitis. Expectant management is the safest approach, because spontaneous rejection of the glue will occur over time. Application of gauze pads coated with antibiotic ophthalmic ointment may speed recovery.²⁵ A thorough eye examination should be performed once the eyelids can be fully opened.

Other xenobiotic-specific treatments have been tried experimentally or clinically,²² but none should be considered prior to, or instead of copious irrigation. Most are not advocated, and consideration of such therapies should be vanishingly rare.

Duration of Irrigation

To accomplish the desired goals of irrigation, the appropriate duration varies with the exposure. Most solvents, for example, do not penetrate deeper than the superficial cornea, and brief (10–20 minutes) irrigation is generally sufficient.²¹ After exposure to acids or alkalis, normalization of the conjunctival pH is often suggested as a useful end point. Testing of pH should be done in every case of acid or alkali exposure, but the limitations of testing must be understood. When measured by sensitive experimental methods, normal pH of the conjunctival surface is 6.5 to 7.6.¹ This is highly method dependent, however, and normal values in the literature range from 5.2 to 8.6.¹⁰ When measured by touching pH-sensitive paper to the moist surface of the conjunctival cul-de-sac, normal pH is most often near 8.³ Therefore, after irrigation following alkali burns, pH should not be expected to reach 7 and is more likely to stabilize near 8.²¹ In this setting, lower pH values may indicate the pH of the irrigant rather than of the ocular surface. Waiting for an interval of several minutes between irrigation and pH testing allows washout of any residual irrigant.¹¹ Choice of testing paper is important, because some are intended for use at extremes of pH and lack sensitivity in the clinically useful range.

Despite these limitations, a logical role for pH assessment can be described. Probably a minimum of 500 to 1000 mL of irrigant should be used for each affected eye before any assessment of pH, and after 7 to 10 minutes, the pH of the lower

fornix conjunctiva should be checked. Thereafter, cycles of 10 to 15 minutes of irrigation followed by rechecks should be continued until the pH is 7.5 to 8. This is certainly adequate for exposures to weak acids, which do not penetrate well, and for alkaline exposures where the pH is less than 12.

For strong or concentrated acid or alkali exposures normal surface pH is not an adequate end point. After these burns, irrigation should be continued for at least 1 to 2 hours, regardless of surface pH, in an attempt to correct anterior chamber pH.^{21,36,44} In addition, immediate ophthalmologic consultation is mandatory. Following this lengthy irrigation, it is important to verify that conjunctival pH has normalized. If not, irrigation must be continued, sometimes for 24 to 48 hours.

Others

Most solvents cause immediate pain and superficial injury because of dissolution of corneal epithelial lipid membranes but do not penetrate or react significantly with deeper tissue.²¹ The epithelial defect may be large or complete, but the limited depth of injury usually allows rapid regeneration of normal epithelium. Detergents and surfactants cause variable injury, ranging from minor irritation from soaps to extensive injury from cationic detergents such as concentrated benzalkonium chloride.²¹ Ocular exposure to A-200 Pyrinate pediculicide shampoo causes typical detergent–surfactant injury, leading to extensive loss of corneal epithelium but with normal underlying stroma; therefore, complete healing within days. Lacrimators (tear gases), such as chloroacetophenone, stimulate corneal nerve endings and cause pain, burning, and tearing, but produce no structural injury at low concentrations. At high concentrations, these xenobiotics can produce significant corneal injury.

Pepper spray, often used for self-protection by civilians or to defuse a potentially violent event by law enforcement contains the active ingredient oleoresin capsicum (OC). OC results in rapid depolarization of nociceptors containing substance P, resulting in immediate pain, blepharospasm, tearing, and blurred vision. In general, ocular injury is uncommon, although corneal erosions can occur. The solvent used for the spray can be more injurious to the eye than the OC itself. Although most sprays use a water-based or oil-based solvent, some use alcohol, which can result in significant corneal damage.⁴⁷ Management of pepper spray exposure consists of rapid irrigation and pain control. Corneal erosions can be treated with artificial tears but corneal abrasions should be treated with topical antistaphylococcal antibiotics. Specific information on thousands of other xenobiotics is readily available if needed.²¹

General Measures

There is a wide array of options for adjunctive therapy of chemical burns of the eye. In all cases in which serious injury is evident, the treatment plan must include consultation with an ophthalmologist. Generally, patients with corneal injury should be treated with an ocular topical antibiotic providing antistaphylococcal and antipseudomonal coverage. Cycloplegics not only reduce pain from ciliary spasm, but also decrease the likelihood of posterior synechiae (scar) formation. Topical nonsteroidal antiinflammatory drugs and systemic analgesics also improve patient comfort. It is never appropriate to dispense topical ophthalmic anesthetics, because repeated use leads to further corneal disruption both by direct chemical effects and by eliminating corneal protective reflex sensation.

DISPOSITION

Disposition of patients with chemical burns of the cornea can be challenging. Patients with extensive burns to other parts of the body should be evaluated for transfer to a burn center. Grading the degree of injury in patients with isolated ocular injury can guide disposition. The most commonly used grading system is the Roper-Hall modification of the Ballen classification system. Injury is graded on a four-tier scale. Patients with mild conjunctival injection with corneal epithelial loss and minimal corneal haziness are classified as grades 1 and 2 (mild to moderate). These patients can be safely discharged from the emergency department with ophthalmology follow-up within 24 to 48 hours. Patients with severe corneal haziness or opacification with significant limbal ischemia are classified as grades 3 or 4 (moderate to severe) and should receive immediate consultation with an ophthalmologist; transfer to a burn unit should be considered.

SYSTEMIC ABSORPTION AND TOXICITY FROM OCULAR EXPOSURES

Systemic absorption from ocular exposure has caused serious toxicity, morbidity, and even death.^{14,23} Although the patterns of toxicity are characteristic of the xenobiotics involved, recognition may be delayed as a result of a failure to appreciate the eye as a significant route of absorption. Although transcorneal diffusion of xenobiotics is limited, there is substantial nasal mucosal absorption after nasolacrimal drainage, and absorption via conjunctival capillaries and lymphatics, which is markedly increased during conjunctival inflammation. Unlike the gastrointestinal route of absorption, there is no significant first-pass hepatic removal after ocular absorption; consequently, bioavailability is much greater.^{20,23,39} If nasolacrimal outflow is normal, up to 80% of instilled drug may be absorbed systemically.¹⁴ Unfortunately, by the time toxicity is apparent, there is no role for ocular decontamination to prevent further absorption. After instillation of eyedrops,

absorption is generally complete within 7 minutes.

Children appear to be at greatest risk, possibly because of the higher relative drug dose they experience when systemic absorption does occur.^{14,34,39} Diligent attempts to comply with prescribed dosing in a struggling, crying infant may also result in excessive dosing. As eyedrop size (40–50 μL) exceeds ocular cul-de-sac capacity (30 μL), overflow often occurs and is assumed to represent a failed instillation, which leads to unnecessary reinstallation. Also, as doses of ocular medications are typically not adjusted based on patient weight, the consequences of equivalent degrees of systemic absorption are much greater for an infant than for an adult. Toxicity from eyedrops is also a problem among the immunocompromised, probably because of the combination of greater use of potentially toxic ophthalmic medications and the presence of comorbid conditions.

Prevention of systemic toxicity from topical ophthalmic medications requires recognition of the risk, a careful history, use of the lowest effective concentration and dose, and patient education including proper administration instructions. To minimize inadvertent absorption, no more than one drop of any eyedrop solution should be instilled at one time in the superolateral corner of the eye while using gentle finger compression of the medial canthus to limit nasolacrimal drainage.^{14,23}

Mydriatics

Mydriatics are used almost exclusively to dilate the pupils prior to diagnostic evaluation of the eyes. This common practice is not generally considered to be potentially dangerous; however, the risk may be substantial if the precautions outlined are not considered. Anticholinergic poisoning (Chap. 49), is well described after ocular use of atropine, cyclopentolate, or scopolamine eyedrops, especially in infants.

The use of the α -adrenergic agonist phenylephrine eyedrops in a 10% solution may cause severe hypertension, subarachnoid hemorrhage, ventricular dysrhythmias, and myocardial infarction.¹⁷ Fortunately, these effects are rare if the 2.5% ocular phenylephrine is used. Mydriatics can also precipitate acute angle closure glaucoma in susceptible individuals.

Miotics and Other Antiglaucoma Drugs

Miosis can be induced by the cholinesterase inhibitor echothiophate (sometimes used to treat glaucoma or accommodative esotropia) which can also exacerbate asthma, parkinsonism, and cardiac disease, and prolong the metabolism of certain medications such as succinylcholine.²³ Miosis can also be produced by use of direct cholinergic agonists, such as pilocarpine. Although absorption is limited, nausea and abdominal cramps can occur at recommended doses. After excessive dosing, salivation, diaphoresis, bradycardia, and hypotension may occur.

β -Adrenergic antagonists, such as timolol, levobunolol, metipranolol, carteolol, and betaxolol, are used to lower intraocular pressure but may cause a variety of adverse effects, including bradycardia, hypotension, myocardial infarction, syncope, transient ischemic attacks, congestive heart failure, exacerbation of asthma, and respiratory arrest. Timolol can exacerbate weakness in patients with myasthenia gravis and is implicated in both causing and masking symptoms of hypoglycemia in diabetics.^{41,42} Nonspecific complaints of anorexia, anxiety, depression, fatigue, hallucinations, headache, and nausea are also described after use of timolol eye drops. Despite the cardioselectivity of betaxolol, respiratory effects occur.¹⁴

Dipivefrin, an esterified epinephrine derivative sometimes used to treat glaucoma, can cause systemic adrenergic effects, although much fewer than those caused by epinephrine. Ophthalmic formulations of highly selective α_2 -adrenergic agonists, brimonidine (Alphagan) and apraclonidine (Iopidine), were introduced to treat glaucoma.^{14,45} Apraclonidine is expected to have a lower potential for toxicity because of limited CNS penetration. Systemic absorption of brimonidine eye drops in a child has led to bradycardia, hypotension, and a decreased level of consciousness, similar to the central effects of other α_2 -adrenoceptor agonists (eg, clonidine),⁶ apparently mediated through both α_2 -adrenoceptors and imidazoline receptors⁸ (Chap. 63).

Antimicrobials

Life-threatening reactions to ophthalmic antimicrobials are unusual. Aplastic anemia has occurred after prolonged use of chloramphenicol eye preparations,¹⁵ and Stevens-Johnson syndrome was reported after short-term use of ophthalmic sulfacetamide in a patient with a history of allergy to sulfa drugs.²⁰

TOXICITY TO OCULAR STRUCTURES FROM NONOCULAR EXPOSURES

Ocular toxicity from systemic xenobiotics is almost always the result of chronic exposure, and the manifestations develop over a prolonged period of time. Thousands of xenobiotics are implicated, affecting every element of the visual system

from the cornea to the optic cortex. Thorough discussion of this topic is beyond the scope of this text, but [Table 25–2](#) lists examples of causative xenobiotics.^{17,21} Many topical and systemic medications are associated with inflammation of the eye, such as uveitis (inflammation of the iris, ciliary process, or choroid membrane).¹⁸ Unlike many other ocular abnormalities caused by xenobiotics, uveitis should prompt immediate ophthalmologic consultation. Because in many cases the etiology is related to commonly prescribed medications, adverse drug effects should always be considered when patients present with visual abnormalities or unusual ocular findings.

In the setting of emergency care, xenobiotic-induced disturbances of normal vision from systemic exposures take many forms. Impaired near-vision from mydriasis, and diplopia or nystagmus from interference with normal control of extraocular movements, are examples of common, usually harmless visual effects. Serious effects generally result from injury or dysfunction of the neural elements from the retina to the cortex. Such toxicity can be direct (neurotoxic) or indirect (hypoxia, ischemia). Many xenobiotics historically reported to cause acute visual loss directly are no longer available.²¹ Methanol and quinine are currently the most important xenobiotics that cause direct visual toxicity after acute oral poisoning. Many xenobiotics capable of causing vasospasm, hypotension, or embolization also cause acute visual loss ([Table 25–4](#)).⁴⁰ Blindness and other visual defects are described following recovery from severe toxicity with barbiturates and other sedative–hypnotics, opioids, carbon monoxide, and many others.²¹

TABLE 25–4. Xenobiotics Reported to Cause Visual Loss after Acute Exposures	
Direct Causes	Indirect Causes ^b
Caustics	Vasoactive xenobiotics
Methanol	Amphetamines
Quinine	Cocaine
Lead ^a	Ergot alkaloids
Mercuric chloride ^a	Hypotension (eg, calcium channel blockers)
	Cisplatin
	Combined endocrine xenobiotics (thyrotropin-releasing hormone with gonadotropin-releasing hormone and glucagon)
	Embolization of foreign material (intravenous injection)

^aDistinctly rare with poisoning. ^bDistinctly rare with use of these xenobiotics; visual loss often instantaneous, secondary to sudden hypotension, vascular spasm, or embolization.

OCULAR COMPLICATIONS OF DRUG ABUSE

In addition to the well-known ocular pupillary signs of opioid, cocaine, amphetamine, and phencyclidine toxicity, a number of complications may result from short-term or long-term use of these and other xenobiotics.³¹ Quinine amblyopia ([Chap. 59](#)) caused by intravenous use of quinine-containing heroin is one of many ocular complications caused by injection of contaminants. Talc contaminants have resulted in talc retinopathy, which was first described after prolonged intravenous use of adulterated methylphenidate¹⁹ but was also noted after intravenous use of heroin, methadone,³² codeine, meperidine, and pentazocine. Talc retinopathy develops only after extensive intravenous drug use. In one study of intravenous methadone abusers, only patients who had injected more than 9000 tablets developed this complication.³² Infectious complications, such as fungal (*Candida*, *Aspergillus*) or bacterial (*Staphylococcus* spp, *Bacillus cereus*) endophthalmitis, are well known as both direct effects of intravenous drug use and secondary complications of acquired immunodeficiency syndrome (AIDS). In addition to AIDS-related ophthalmic infections such as cytomegalovirus, cryptococcus, toxoplasmosis retinitis, and choroidal *Mycobacterium avium-intracellulare* complex (MAC), other disorders include retinal cotton-wool spots, conjunctival Kaposi sarcoma, and ocular motility disorders caused by infectious or neoplastic meningitis. Corneal defects are reported after smoking cocaine alkaloid (“crack eye”).³⁷ Cocaine that is either volatilized or inadvertently introduced by direct contact probably results in corneal anesthesia and loss of corneal protective reflex sensation. Minor trauma, such as eye rubbing, then leads to corneal epithelial defects. In addition, there appears to be an increased incidence of infectious keratitis and corneal ulceration in these patients. The ability of local anesthetics to interfere with corneal epithelial adhesion may also play a role.

SUMMARY

- Systemic and local toxicologic emergencies are manifest in the ophthalmic system.

- Although the obvious physical injuries are apparent to the clinician, the more subtle clues to toxicologic mechanisms that involve the ophthalmic and neurologic systems are made only by a meticulous examination of the eye.
- Direct ocular toxins should be washed out immediately without delays for determining visual acuity or locating toxin specific irrigation solutions.
- After initial management, patients with moderate-severe injury should be promptly referred to an ophthalmologist for further evaluation.

26 OTOLARYNGOLOGIC PRINCIPLES

William K. Chiang

Many xenobiotics adversely affect the senses of olfaction, gustation, and cochlear-vestibular functions. These toxic effects are not life-threatening but may pose significant distress to patients. Health care providers are often not familiar with the pathophysiology of these special senses. Furthermore, because of the lack of standardized diagnostic techniques and normal parameters, such adverse effects may be overlooked and dismissed by health care providers, despite significant patient distress and dysfunction. This is particularly true for disorders of olfaction and gustation. This chapter reviews the anatomy and physiology of these senses, describes the effects of xenobiotics on these senses, and examines the significant diagnostic information these senses contribute to identifying the presence of xenobiotics. Understanding the effects of xenobiotics on these senses may allow for early detection, removal, appropriate referral, treatment, and prevention of future events. In occupational settings, understanding these principles may prevent permanent and life-threatening injuries.

OLFACTION

Anatomy and Physiology

Olfactory receptors are bipolar neurons located in the superior nasal turbinates and the adjacent septum. There are 10 to 20 million receptor cells per nasal chamber, and the receptor portion of the cell undergoes continuous renewal from the olfactory epithelium.^{114,118} Renewed olfactory receptors regenerate neural connections to the olfactory bulb. These olfactory receptor neurons are distinctive in their ability to regenerate.²⁴ The axons of these cells form small bundles that traverse the fenestrations of the cribriform plate of the ethmoid bone to the dura. Within the dura, these bundles form connections with the olfactory bulb from which neural projections then connect to the olfactory cortex. There are extensive interconnections to other parts of the brain, such as the hippocampus, thalamus, hypothalamus, and frontal lobe, suggesting effects on other biologic functions.¹¹⁴ Although primary odor detection is a function of the olfactory nerve (CN I), some irritant odors, such as ammonia and acetone, are transmitted through the trigeminal nerve (CN V) and its receptors.^{45,153}

The actual olfactory receptor sites are structurally similar to the taste receptors of the mouth and the photoreceptors of the retina. The receptor is a single polypeptide chain consisting of approximately 350 amino acids, which folds back and forth onto itself to traverse the cellular membrane seven times. The outer end of the polypeptide contains an amine group (N-terminal) and the cytosolic end contains a carboxyl group (C-terminal). The transmembranous portions determine the receptor shape and characteristics of the binding site. When a molecule binds to a specific receptor site, the resultant conformational change leads to the activation of the G protein system and calcium and/or sodium channel activation and neurotransmission.⁷⁹

Smelling is an extremely sensitive mechanism of detecting xenobiotics. Olfactory receptors can detect the presence of a few molecules of certain xenobiotics with a sensitivity that is superior to some of the most sophisticated laboratory detection instruments.⁷²

Clinical Use of Odor Recognition

The sense of smell can be extremely useful as a toxicologic warning system. Human olfaction is a variable trait.^{5,126,187} For example, 40% to 45% of people have specific anosmia (inability or loss of smell) for the bitter almond odor of cyanide.^{46,94,126} There are limited data on the inheritance characteristics or genetic basis of these specific forms of anosmia. While some studies suggest that the ability to detect the odor of cyanide is a sex-linked recessive trait,⁶² other studies yield conflicting results.^{5,19,96} Women have a greater ability to detect androsterone, which is prominent in human underarm secretion.⁷² Human olfaction usually can distinguish a mixture of no more than four xenobiotics¹⁰⁰; therefore, specific odors may be masked by other stimuli.

Olfactory fatigue is the process of olfactory adaptation following exposure to a stimulus for a variable period of time. This leads to a temporal diminution of the smell. Unfortunately, this adaptation may provide a false sense of security during continued exposure to a xenobiotic. For example, hydrogen sulfide, which inhibits cytochrome oxidase, is readily detectable as distinct and offensive at the very low concentration of 0.025 ppm. At the higher and potentially toxic

concentration of 50 ppm, the odor is less offensive, and recognition may disappear after 2 to 15 minutes of exposure.^{8,160} At even higher concentrations when toxicity is likely, the onset of olfactory fatigue is even more rapid. The combination of the rapid onset of olfactory fatigue and systemic toxicity at high concentrations of hydrogen sulfide exposure has contributed to numerous fatalities (Chap. 126).^{1,25,174}

In industrial settings, it is important to be aware of impaired olfactory function in any worker who may be exposed to chemical vapors or gases.^{77,166} Such workers are at increased risk for toxic injury. The National Institute for Occupational Safety and Health (NIOSH) requires that an individual using an air-purifying respirator be capable of detecting the odor of a xenobiotic at concentrations below those producing toxicity.^{6,166} Sensory perception at this concentration ensures that the individual can detect filter cartridge “breakthrough” or failure at a safe concentration.¹⁶⁶ The odor safety factor refers to the ratio of the time-weighted average (TWA) threshold limit value (TLV) to the odor threshold for a given xenobiotic. A xenobiotic with a high odor safety factor can be detected despite prolonged exposure.⁶ Nontoxic xenobiotics with a very high odor safety factor, such as ethyl mercaptan, can be added to xenobiotics that are odorless with lower safety factors so that olfactory detection is predictable. This enhanced sensory awareness is the basis for the addition of mercaptans to the odorless natural gases used in the home so as to limit the potential for unrecognized hazardous exposure.

The recognition of odors has traditionally been considered an important diagnostic skill in clinical medicine. Some diseases can be diagnosed accurately by recognizable associated odors of various affected parts of the body such as the breath, sweat, urine, and wounds: diabetic ketoacidosis as a characteristically fruity odor; diphtheria as sweet; scurvy as putrid; typhoid fever as fresh-baked brown bread; and scrofula as stale beer.³⁹ Odors are also described for disorders of amino acid and fatty acid metabolism, such as phenylketonuria, maple syrup urine disease, hypermethioninemia, and isovaleric acidemia.³⁹

The recognition of odors continues to be an important diagnostic skill for the rapid detection of some xenobiotics (Table 26–1). To increase awareness of odors of toxic xenobiotics, a “sniffing bar” of commonly available odors may be prepared.⁶⁷ Nontoxic xenobiotics that simulate the odors of toxic xenobiotics are placed in test tubes, numbered, and inserted in a test tube rack for circulation among staff. The sniffing bar, brief descriptions of clinical presentations, and a table of diagnostic odors (Table 26–1) may be used to teach the recognition of odors in medical toxicology.⁶⁷

TABLE 26–1. Odors Suggestive of a Xenobiotic

<i>Odor</i>	<i>Xenobiotic</i>
Bitter almond	Cyanide
Carrots	Cicutoxin (water hemlock)
Disinfectants	Creosote, phenol
Eggs (rotten)	Carbon disulfide, disulfiram, hydrogen sulfide, mercaptans, <i>N</i> -acetylcysteine
Fish or raw liver (musty)	Aluminum phosphide, zinc phosphide
Fruity	Nitrites (amyl, butyl)
Garlic	Arsenic, dimethyl sulfoxide, organic phosphorus compounds, phosphorus, selenium, tellurium, thallium
Hay	Phosgene
Mothballs	Camphor, naphthalene, <i>p</i> -dichlorobenzene
Pepper	<i>O</i> -chlorobenzylidene malononitrile
Rope (burnt)	Marijuana, opium
Shoe polish	Nitrobenzene
Sweet fruity	Acetone, chloral hydrate, chloroform, ethanol, isopropanol, lacquer, methylbromide, paraldehyde, trichloroethane
Tobacco	Nicotine
Vinegar	Acetic acid
Violets	Turpentine (metabolites excreted in urine)
Wintergreen	Methyl salicylate

Classification of Olfactory Impairment

There are different types of olfactory dysfunction. Anosmia, the inability to detect odors, and hyposmia, a decrease in the perception of certain odors, are the most common forms of olfactory impairment. The etiology of olfactory impairment may be classified as conductive, from anatomic obstruction of inspired air, or perceptive, from dysfunction of the olfactory receptors or signal transmission. Most conductive olfactory dysfunction results in hyposmia, because the obstruction is usually incomplete.^{114,150}

The most common causes of anosmia and hyposmia are viral infections, trauma, xenobiotics, tumors, and congenital and psychiatric disorders (Table 26–2).^{45,136,142,150} Viral infections may result in olfactory impairment either by obstructing nasal airflow or by causing damage to the olfactory epithelium.⁸⁰ Trauma to the head or nose can shear fragile olfactory nerves crossing the cribriform plate.^{153,176}

TABLE 26–2. Xenobiotics Responsible for Disorders of Smell

<i>Hyposmia/Anosmia</i>	<i>Dysosmia/Cacosmia/Phantosmia</i>
Acrylic acid	β-Adrenergic antagonists
Antihyperlipidemics: cholestyramine, clofibrate, gemfibrozil, HMG-CoA reductase inhibitors	Amebicides/antihelminthics: metronidazole
Cadmium	Anesthetics, local
Chlorhexidine	Anticonvulsants: carbamazepine, phenytoin
Cocaine	Antihistamines
Formaldehyde	Antihypertensives: angiotensin-converting enzyme inhibitors, diazoxide
Gentamicin nose drops	Antimicrobials
Hydrocyanic acid	Antiinflammatory
Hydrocarbons (volatile)	Antirheumatics: allopurinol, colchicine, gold, D-penicillamine
Hydrogen sulfide	Antiparkinsonians: levodopa, bromocriptine
Methylbromide	Antithyroid drugs: methimazole, methylthio- uracil, propylthiouracil
Nutritional	Calcium channel blockers
Vitamin B ₁₂ deficiency	Dimethylsulfoxide
Zinc deficiency	Ethacrynic acid
Pentamidine	Insecticides
Sulfur dioxide	Lithium
	Nicotine
	Opioids
	Sympathomimetics
	Toothpastes
	Vitamin D

Anosmia = the loss of smell; cacosmia = sensation of a foul smell; dysosmia = a distorted perception of smell; hyposmia = a decreased perception of smell; phantosmia = sensation of smell without stimulus.

Chronic exposures to numerous xenobiotics are associated with olfactory dysfunction (Table 26–2). The most common toxic mechanism related is perceptive olfactory dysfunction. This may be a result of a direct injury, or of a structural alteration of the receptor or its components such as G proteins, adenylate cyclase, or receptor kinase.^{78,79} Anosmia or hyposmia from hydrocarbons, formaldehyde, cadmium, and chemotherapeutics such as cytarabine results from direct effects on the receptor sites.^{49,79,84} Local effects on the epithelium and the receptors from antibiotic nose drops may lead to temporary anosmia and hyposmia.^{90,186} Inhaled corticosteroids may have local effects on the epithelium, as well as direct effects on both G proteins and adenylate cyclase.⁸¹ Cocaine insufflation causes direct local effects as well as effects on receptor functions.^{68,70} Because of the limited local effects of most xenobiotics and the regenerative ability of the olfactory receptor neurons, most xenobiotic-induced olfactory dysfunction is reversible.

Many individuals determined to have anosmia actually have congenital anosmia for select molecules, such as hydrogen cyanide, n-butyl mercaptan, trimethylamine, and isovaleric acid.^{7,45} Some extreme forms of congenital anosmia are associated with other abnormalities, such as Kallmann syndrome, a hereditary form of anosmia associated with hypogonadotropic hypogonadism where agenesis of the olfactory bulbs and incomplete development of the hypothalamus are responsible for the anosmia.^{45,153}

Dysosmia or parosmia is the distorted perception of smell (Table 26–2). Subclassifications of dysosmia include the perception of foul smell or cacosmia, the sensation of smell without a stimulus, or phantosmia, and the sensation of the smell of a burnt or metallic material, torquosmia.¹⁵⁰ The etiologies are classified as peripheral or central. Peripheral etiologies include abnormalities of the nose, sinuses, and upper respiratory tract. Central etiologies may be related to disorders such as Addison disease, hypothyroidism, temporal lobe epilepsy, psychosis, or pregnancy.^{45,114,151} How these conditions actually alter the perception of smell is unclear. A number of xenobiotics with similar effects are listed in Table 26–2. Bromocriptine alters dopaminergic transmission and inhibits adenylate cyclase. Levodopa affects the dopaminergic transmission and also chelates zinc, which is important in the maintenance of normal receptor functions.^{79,81}

Evaluation of Olfactory Impairment

General evaluation of olfactory function should include a detailed history, focusing on types, duration, and progression of symptoms, recent illnesses, head and nose trauma, sinus problems, family history, occupational history, hobbies, and xenobiotic history.^{41,71} A physical examination with a detailed examination of the nasopharynx and sinuses should be performed to assess the potential for inflammation or structural abnormality. A simple set of olfactory stimulants, such as ground coffee, almond extract, peppermint extract, and musk, should be used to test each nostril individually with the patient's eyes closed.^{71,153} Standardized smell tests such as the UPSIT (University of Pennsylvania Smell Identification Test) and the CCCRC (Connecticut Chemosensory Clinical Research Center) tests are commercially available, and a composite score based on a panel of tests can determine the degree of olfactory dysfunction.¹⁰⁶ Pungent odors or stimulation associated with ammonia, capsaicin, acetone, and menthol are dependent on the trigeminal nerve (CN V) olfactory function, which is mainly responsible for tactile pressure, pain, and temperature sensation in the mouth and nasal cavity. A patient who has olfactory nerve damage should be able to detect these substances; conversely, a person with hysteria may deny detection of these substances that should physiologically be recognized.^{71,153,186} If a xenobiotic-mediated mechanism is suspected, the offending xenobiotic should be discontinued. Coronal computed tomography of the sinuses and nose or magnetic resonance imaging of the brain should be obtained if structural abnormalities are suspected.^{153,186} Gas chromatographic analysis of the urine may be useful in patients with fish odor syndrome associated with trimethylaminuria.^{101,163} Complicated cases and patients with significant impairment should be referred to an otolaryngologist or neurologist.

GUSTATION

Anatomy and Physiology

Taste, the sensory interpretation of oral materials, is determined by taste buds on the tongue, palate, throat, and upper third of the esophagus. The cells in the taste buds have a life span of 10 days and are constantly renewed.^{11,153} The taste buds on the anterior two-thirds of the tongue and the palate are innervated by the facial (CN VII) nerve, those on the posterior one-third of the tongue by the glossopharyngeal (CN IX) nerve, and those on the laryngeal and epiglottal regions by the vagus (CN X) nerve. The signals are sent to the solitary nucleus in the brainstem, where they are processed and distributed to various regions of the brain. There are at least 13 known chemical taste receptors responsible for the five primary taste sensations—sweet, sour, bitter, umami (savory) and salty: two sodium receptor types; two potassium receptor types; one chloride receptor; one adenosine receptor; two inosine receptor; two sweet receptor types; two bitter receptor types; one glutamate receptor; and one hydrogen ion receptor.⁷³ One substrate will typically activate multiple taste receptors; the combined effects of these stimulated receptors determine the taste of the substance.⁶⁰

The structure of the taste receptors is similar to that of the olfactory receptors, in that they are coupled to G proteins and sodium and calcium channels permitting neural stimulation. Each receptor is capable of interacting with various classes of xenobiotics, of varying sizes. The pH of the xenobiotic determines sour (acid taste), whereas sodium or potassium concentrations determine salty taste. Many xenobiotics such as sugars, glycols, aldehydes, ketones, amides, amino acids, inorganic salts of lead, and bretylium activate the sweet receptors. Bitter taste may result from long-chain organic substances containing nitrogen, or alkaloids, including quinine, strychnine, caffeine, and nicotine.^{13,73} The threshold for bitter receptor stimulation is several orders of magnitudes lower than other taste receptors.¹³ Umami taste is a more recently accepted primary taste, best defined as a pleasant savory taste. The primary xenobiotic that stimulates umami receptor is glutamate, such as monosodium-L-glutamate. Umami receptor stimulation can be enhanced by 5'-ribonucleotide monophosphates such as inosine and guanosine.¹⁹⁰ Salivary proteins, such as zinc-containing gustin and ebnerin, are important in the regulation of taste sensation.^{79,83,103,161} These molecules may serve as binding proteins and growth factors for the regeneration of taste receptors. Taste is also affected significantly by the appreciation of aromas or odors and, to a lesser extent, by visual perception.¹⁵¹

Classification of Gustatory Dysfunction

Types of gustatory dysfunction include ageusia, the inability to perceive taste; hypogeusia, the diminished sensitivity of taste; and dysgeusia, the distortion of normal taste. There are several variations of dysgeusia, such as cacogeusia, which is a perceived foul, perverted, or metallic taste.^{71,111} Taste impairment is commonly related to direct damage to the taste receptors, adverse effects on their regeneration, or effects on receptor mechanisms.⁸⁰ These effects can result from a xenobiotic, disease, aging, and nutritional disorder (Table 26–3).^{66,73,141,172} Any abnormality that interferes with either the direct contact of a xenobiotic with the gustatory cells of the tongue or cranial nerves VII, IX, or X dramatically affects taste.¹⁵⁰ Most common forms of xenobiotic-induced dysgeusia are related to direct effects on the taste receptor site or effects related to receptor mechanisms such as G proteins, adenylate cyclase, and calcium channels.⁹⁹ Other forms of dysgeusia may result from direct stimulation of chemical receptors by xenobiotics.^{73,79}

TABLE 26–3. Xenobiotics Responsible for Alterations of Taste

<i>Hypogeusia/Ageusia</i>	<i>Dysgeusia</i>	<i>Metallic Taste</i>
Local	Local	ACE inhibitors
Chemical and thermal burns	Chemical burn	Acetaldehyde
Radiation therapy	Radiation therapy	Allopurinol
Systemic	Systemic	Arsenicals
ACE inhibitors	ACE inhibitors	Cadmium
Amiloride	Adriamycin	Ciguatoxin
Amrinone	Amphotericin B	Copper
Carbon monoxide	Botulism (in recovery)	<i>Coprinus</i> spp
Cocaine	Carbamazepine	Dipyridamole
Dimethylsulfoxide	Dimethylsulfoxide	Disulfiram
Gasoline	5-Fluorouracil	Ethambutol
Hydrochlorothiazide	Griseofulvin	Ferrous salts
Methylthiouracil	Isotretinoin	Flurazepam
Nitroglycerin	Levodopa	Iodine
NSAIDs	Nicotine	Lead
Penicillamine	Nifedipine	Levamisole
Propranolol	NSAIDs	Lithium
Pyrethrins	Phenylthiourea (hereditary)	Mercury
Smoking	Quinine	Methotrexate
Spironolactone	Zinc deficiency	Metformin
Triazolam		Metoclopramide
		Metronidazole
		Pentamidine
		Pine nuts
		Procaine penicillin
		Propafenone
		Snake venom
		Tetracycline

ACE = angiotensin-converting enzyme; NSAID = nonsteroidal antiinflammatory drug.

Angiotensin-converting enzyme (ACE) inhibitors commonly cause gustatory impairment, usually hypogeusia and dysgeusia.^{18,68,113,188} ACE inhibitors work by inhibiting zinc-dependent ACE, and chelating zinc from taste receptors and salivary proteins results in gustatory dysfunction. Calcium channel blockers act by inhibiting calcium channels of the taste receptor mechanisms.⁷³ Many diuretics cause zinc depletion by enhancing zinc elimination in the urine,⁷⁹ whereas furosemide and spironolactone may also chelate zinc. Numerous xenobiotics also cause gustatory dysfunction through variable degrees of zinc chelation: amrinone, ethambutol, hydralazine, methyl dopa, the nonsteroidal antiinflammatory drugs (NSAIDs), antithyroid agents, penicillamine, and phenytoin.^{73,79,189} Arsenic, mercury, chromium, and lead may either chelate zinc or replace zinc in salivary proteins because of a higher level of affinity. Chemotherapeutics and colchicine inhibit cellular division and taste-receptor regeneration. The oral antiseptic chlorhexidine directly alters taste-receptor function.⁵⁸ Acetazolamide causes cacogeusia when carbonated beverages are consumed. The exact mechanism is unclear, but is postulated to be a result of the inhibition of carbonic anhydrase causing carbon dioxide accumulation and an increased tissue bicarbonate.^{79,92,115}

HEARING

Anatomy and Physiology

Normal hearing begins when sound waves are captured by the external auricle, traverse the external auditory canal, and are conducted to the tympanic membrane, the three auditory ossicles of the middle ear, and move through the oval window to the perilymph in the scala vestibuli of the cochlea (Figs. 26–1 and 26–2). The sound wave is then transferred through the Reissner membrane at the roof of the cochlear duct, to the endolymph and the organ of Corti.^{54,167} The specialized hair cells

of the organ of Corti convert mechanical waves into neurologic signals. The hair cells contain cross-linked stereocilia projections that detect transmitted shear forces, which lead to the influx of potassium from the endolymph through opened potassium channels.^{43,104} Depolarization of the hair cells results in calcium influx and neurotransmitter release to the cochlear nerve. Neurologic signals from the cochlear nerve are conducted to the cochlear nucleus of the pons; bilateral projections are then sent to the superior olivary nucleus of the midbrain, nuclei of lateral lemnisci, inferior colliculus, medial geniculate body of the thalamus, and then to the auditory cortex of the temporal lobe.¹⁶⁷ Interruption or damage to any part of the hearing mechanism may lead to auditory impairment.

FIGURE 26–1. Pathways of sound conduction in the ear.

FIGURE 26–2. Cross-section of the organ of Corti showing sites of xenobiotic effect.

The anatomy and physiology of the cochlea and its importance in the biomechanics of hearing are reviewed in order to better understand the potential for xenobiotic injury. The word cochlea is derived from the Greek word *kochlias*, meaning snail, and describes its general structure—a 2.5-turn, spirally wound tube. The cochlea is further divided into three inner tubular structures: the upper tube or scala vestibuli, the middle tube or cochlear duct, and the lower tube or scala tympani. The scala vestibuli and the scala tympani contain the perilymph fluid. The cochlear duct contains endolymph fluid, the Reissner membrane at the roof, and the organ of Corti.¹⁶⁷ The cochlear fluids serve multiple functions: to conduct sound waves to the hair cells; to provide nutrients for and remove waste from the cells lining the cochlear duct; to control pressure distribution in the cochlea; and to maintain an electrochemical gradient for the function of the hair cells. The sodium concentration of the perilymph is similar to that of the extracellular fluid, and the potassium concentration of the endolymph is similar to that of the intracellular fluid.⁵⁶ Any significant alterations of the sodium or potassium concentrations will depress the cochlear potential and function. The stria vascularis controls the production of the cochlear fluids and the repolarization of the hair cells, and maintains the electrochemical gradient between the endolymph and the perilymph. The stria vascularis contains a high concentration of the oxidative enzymes, $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase (ATPase), adenylate cyclase, and carbonic anhydrase, which are all highly susceptible to xenobiotics.^{20,84,148}

Although human speech is composed of sounds in the frequency of 250 to 3000 Hz, humans can normally detect sounds in the frequency range of 20 to 20,000 Hz.¹²⁵ The cochlea is a “tuned” structure with varying width and stiffness, such that different regions can receive different sound waves. The stiffer and wider base of the cochlea serves as a receptacle for higher-frequency sounds, whereas the apex is responsible for receiving the lower-frequency sounds.⁵⁴ Because various regions of the cochlea are susceptible to different forms of injury, appropriate audiologic testing should be tailored specifically to each patient.²⁷

Xenobiotic-Induced Ototoxicity

Ototoxicity includes effects on the cochlear and vestibular system. This section focuses on cochlear toxicity. Quinine and salicylates were widely recognized in the 1800s and streptomycin in the 1940s as causes of ototoxicity.^{85,143} Several hundred xenobiotics are implicated as causes of either reversible or irreversible ototoxicity (Table 26–4).^{23,89,97,121} Ototoxic xenobiotics primarily affect two different sites in the cochlea: the organ of Corti—specifically the outer hair cells—and the stria vascularis. Because of the limited regenerative capacity of the sensory hair cells and other supporting cells, when significant cellular damage occurs, the loss is often permanent.^{47,54,85,165} Although cell death of the outer hair cells

from inflammation and necrosis is expected when sufficient insults occur, apoptotic cell death is now postulated to be a major mechanism of ototoxicity from certain xenobiotics such as cisplatin and aminoglycosides.^{20,23,44,85,89,140} Inhibition of caspases and calpain associated with apoptosis of the hair cells is demonstrated to decrease ototoxicity from cisplatin and aminoglycosides in animals.^{140,164} Heat shock proteins are endogenous molecules that respond to cellular stress and inhibit apoptosis. Xenobiotics that can up-regulate heat shock proteins such as celestrol prevent cisplatin and aminoglycoside toxicity in animal models.^{40,59} Further studies are required to demonstrate clinical utility. Evidence supports the concept that otic injury can be potentiated by loud noises. Although the actual cellular mechanisms for many forms of ototoxicity remain unclear,¹⁸⁵ some of the mechanisms are known.⁶³ Loop diuretics, such as furosemide, bumetanide, and ethacrynic acid, cause physiologic dysfunction and edema at the stria vascularis, resulting in reversible hearing loss.^{85,109,181} The underlying mechanisms appear to be the inhibition of potassium pumps and G proteins associated with adenylate cyclase.⁹ Studies of loop diuretics demonstrate decreased potassium activity in the endolymph and a decreased endocochlear potential.¹⁴⁵ Permanent hearing loss associated with furosemide and ethacrynic acid is also reported, and may be related to direct interference with oxidative metabolism in the outer hair cells.^{98,109,145}

TABLE 26–4. Etiologies of Xenobiotic-Induced Hearing Loss

<i>Reversible</i>	<i>Irreversible</i>
Antimicrobials: chloroquine, erythromycin, quinine	Aminoglycosides
Carbon monoxide	Chemotherapeutics: bleomycin, cisplatin, nitrogen mustard, vincristine, vinblastine
Cocaine	Bromates
Diuretics: acetazolamide, bumetanide, ethacrynic acid, furosemide, mannitol	Hydrocarbons: styrene, toluene, xylene
Nonsteroidal antiinflammatory drugs	Metals: arsenic, lead, mercury
Opioids (frequently)	Opioids (infrequently)
Salicylates	

Salicylates are a well-known cause of ototoxicity. Aspirin (acetylsalicylic acid)-induced hearing impairment was first reported in 1877.⁹³ Salicylate-induced hearing loss is generally mild to moderate (a loss of 20–40 decibels {dB}) and reversible.^{17,87} Animal studies demonstrate immediate hearing impairment with the use of high doses of salicylates.^{16,110,111,132} The mechanism of salicylate-induced ototoxicity is unclear, although multiple factors are postulated. Salicylates and other NSAIDs inhibit cyclooxygenase, which converts arachidonic acid to prostaglandin G₂ and prostaglandin H₂. These effects may interfere with Na⁺-K⁺-ATPase pump function at the stria vascularis, and also decrease cochlear blood flow.^{29,50,93} A reversible decrease in outer hair cell turgor secondary to membrane permeability changes may impair otoacoustic emissions.^{131,135} In support of these theories, pretreatment of animals with leukotriene antagonists and α -adrenergic receptor antagonists attenuates or prevents salicylate-induced ototoxicity.⁹³

NSAIDs and quinine also cause reversible hearing loss, particularly at the higher frequencies.^{31,85} Occasionally, quinine-induced hearing loss may be permanent.^{85,149} The primary mechanism is related to prostaglandin inhibition.⁹³ Quinine inhibits the enzyme phospholipase A₂, which converts phospholipids to arachidonic acid. Quinine also inhibits calcium channels that interact with prostaglandins.⁹³

Certain chemotherapeutics, such as cisplatin, vinblastine, and vincristine, can cause permanent ototoxicity.⁸⁵ Cisplatin is the most toxic of the group, with clinically apparent hearing loss noted in 30% to 70% of the patients receiving doses of 50 to 100 mg/m². These antineoplastics typically damage the outer hair cells but may also affect the stria vascularis.⁸⁵ The underlying mechanisms may be related to the inhibition of adenylate cyclase in the stria vascularis, the inhibition of protein synthesis, and the formation of oxygen free radicals.^{9,85,155} The generation of oxygen free radicals and the depletion of antioxidants result in the irreversible damage to the hair cells.⁵² Furthermore, cranial radiation will cause synergistic toxicity if radiation precedes cisplatin therapy. Various antioxidants and free radical scavengers prevent cisplatin-induced ototoxicity in animals, perhaps preventing oxidative injury–induced apoptosis to hair cells.^{102,116,119,137,140,144,169,184} Amifostine, a precursor to a thiol free radical scavenger, prevents cisplatin-induced nephrotoxicity, but does not appear to prevent cisplatin-induced ototoxicity.¹⁴⁷

The aminoglycosides are best known for their association with irreversible ototoxicity,¹³⁰ but they are not concentrated in the cochlea. The endolymph concentration of gentamicin is approximately 10% of that in the serum. It is postulated that toxicity is related to the metabolites of aminoglycosides and not the parent compounds because toxicity can be reproduced

in vivo, but not in vitro.¹⁴⁸ Neomycin and kanamycin are the most ototoxic, although all aminoglycosides are potentially toxic.⁹⁸ With the development of the newer aminoglycosides and therapeutic drug monitoring, the incidence of aminoglycoside-related ototoxicity appears to be decreasing. The reported rates of ototoxicity for the more commonly used aminoglycosides gentamicin and tobramycin are between 5% and 8%.¹⁰⁸ In China, where aminoglycosides are readily available as nonprescription medications, as much as 66% of deafness may be directly related to aminoglycoside toxicity.^{61,105} Several uncommon genetic mutations that predispose to aminoglycoside-induced ototoxicity are identified, including A1555G and C1494T mutations.^{57,75} The genetic transmission appears to be maternal via mitochondrial DNA and the defects increase aminoglycoside binding to mitochondrial 12S ribosomal RNA.⁵⁷ These patients may experience rapid and severe hearing loss compared with normal people with a similar aminoglycoside exposure.¹⁴⁰

Several mechanisms of aminoglycoside ototoxicity are postulated, including antagonism of calcium channels of the outer hair cells of the cochlea, blocking transduction of the hair cells and resulting in acute, reversible hearing deficits as well as binding to polyphosphoinositides of cell membranes to alter their functions. Polyphosphoinositides are essential for the generation of the second messengers diacylglycerol and inositol triphosphate and their ultimate cellular function, for the maintenance of lipid membrane structure and permeability, and as a source for arachidonic acid.^{85,140} However, the most important mechanism is that aminoglycosides interact with iron and copper to generate free radicals, damaging the hair cells. Aminoglycosides also inhibit ornithine decarboxylase which is important for cellular recovery following an injury and makes the cell more susceptible to toxicity.¹⁴⁸ The outer hair cells of the cochlea are increasingly susceptible to aminoglycosides and damage progresses from the inner row of the outer hair cells to the basal turn of the cochlea, and, ultimately, to the apex.^{4,7,98,140}

The risks of ototoxicity are increased with a duration of therapy of more than 10 days, concomitant use of other ototoxic xenobiotics, and the development of elevated serum concentrations.^{7,55,146} There is no evidence that single daily dosing of aminoglycosides alters the risk of ototoxicity.^{127,179} Loop diuretics increase aminoglycoside toxicity by increasing aminoglycoside penetration into the endolymph. In animal models, certain free radical scavengers, such as glutathione, amifostine, and deferoxamine, decrease aminoglycoside-induced ototoxicity.^{64,149,170,177,180} Fosfomycin, a phosphonic antibiotic, has limited efficacy in reducing aminoglycoside-induced ototoxicity.¹²⁴ Leupeptin and Z-DEVD-FMK, calpain and caspase inhibitors, respectively, that affect the apoptotic pathway, decrease ototoxicity in animal models.^{32,63,159,164} Further studies are required to determine their applicability to humans. Salicylates, which may act as free radical scavengers in therapeutic concentration, were effective in preventing gentamicin ototoxicity in animals. Two randomized human trials using concomitant salicylate therapy at 1.5 and 3 g/day significantly attenuated gentamicin-induced ototoxicity.^{12,160} Gastric adverse effects, including bleeding, were also more common in the salicylate group. Confirmation of these findings and determining safer alternatives are warranted.

Erythromycin, vancomycin, and their respective analogs are ototoxic. There are a number of reports of hearing loss following erythromycin therapy in humans and an animal study supporting the ototoxic potential. Most deficits in humans are transient, although several cases of permanent hearing loss are reported.^{21,22} The mechanisms of toxicity remain unclear, although the proposed effects are on the central auditory pathways. Erythromycin-induced hearing loss occurs at both lower and higher frequencies for speech, allowing for recognition in the early stages of ototoxicity.²¹ Similarly, both reversible and irreversible ototoxicities from the newer macrolide antibiotics clarithromycin and azithromycin were also reported.

The evidence for vancomycin-induced ototoxicity is less convincing. Although numerous cases of presumed vancomycin-related ototoxicity are reported, concomitant use of other ototoxic antibiotics was common or audiometric studies were not performed. In limited animal studies, vancomycin alone does not induce ototoxicity, but it increases ototoxicity when administered concomitantly with an aminoglycoside. Vancomycin analogs such as teicoplanin and daptomycin probably have similar ototoxic potentials.

Bromates are among the most extensively studied ototoxic xenobiotics.^{31,36,107,133} Bromates are used in hair “neutralizers,” bread preservatives, and as fuses in explosive devices.^{86,133,173} Following bromate administration the stria vascularis and hair cells of the organ of Corti are irreversibly damaged.¹³³ Substantial exposure to bromates may also cause acute kidney injury, which decreases bromate elimination and, in turn, increases its ototoxic potential.^{86,133}

It is intriguing that xenobiotics, such as the bromates, loop diuretics, and aminoglycosides, primarily affect both the cochlea and the kidneys. One possible explanation is that the stria vascularis and the renal tubules have similar functions in maintaining electrochemical gradients.^{124,125} However, renal tubules may regenerate, while damage to the hair cells and the stria vascularis of the cochlea is more likely to be permanent.

Sudden hearing loss is reported with recreational drug use, particularly with cocaine and opioids. For cocaine, the mechanism of injury may be related to cochlear hemorrhage and hypoxia from vasoconstriction.^{37,123,171} While other mechanisms such as a direct effect on the potassium channels in the hair cells and sodium channels of the auditory nerve have been postulated, they are not well elucidated in animal models. Concomitant opioid use and adulterants should be

considered. Various opioids, including heroin, methadone, and hydrocodone, are associated with hearing loss.^{34,154,156,162} Neither the route of use nor the presence of adulterants such as quinine can adequately explain the hearing loss. Most cases of opioid associated hearing loss are reversible, but some are permanent. The mechanisms of opioid associated hearing loss are unclear. One potential mechanism is that the stimulation of opioid receptors in the cochlea inhibits adenylate cyclase activity, leading to hearing loss.⁵³ Various opioid receptors have been identified in the cochlea, such as in the inner hair cells, outer hair cells, and the spiral ganglion. Others postulate that opioids have potential roles as neurotransmitters or neuromodulators that affect auditory function.⁹¹

Other xenobiotics implicated as ototoxins are carbon monoxide, lead, arsenic, mercury, toluene, xylene, and styrene.^{82,166} However, both human and animal data are quite limited. Carbon disulfide, carbon tetrachloride, and trichloroethylene are also suspected of being ototoxic, but toxicity has not been demonstrated in humans.^{82,156} Because exposures to xenobiotics are frequently occupational, they are of great concern as they may potentiate or be additive to other types of occupational hearing impairments.^{95,138}

High-frequency hearing is most vulnerable, and early or limited impairment may not be noticeable unless audiometry, especially at 8000 kHz and above, is performed.¹⁷⁸ These hearing tests can be performed in infants using the measurement of auditory brainstem response.¹⁴

Noise-Induced Hearing Impairment

Noise-induced hearing impairment has been recognized for hundreds of years, but became a great concern and increasingly prevalent with the industrial revolution and the discovery of gunpowder.⁵⁴ Some of the anatomic changes in the organ of Corti and the audiometric features of noise-induced hearing impairment were well described by 1900.^{2,3,112} Unfortunately, few longitudinal studies on noise-induced hearing impairment have been performed.

Although noises of sufficient magnitude may cause hearing impairment with limited exposure, most noise-induced hearing losses result from preventable prolonged cumulative occupational exposure. NIOSH has estimated that up to 1.7 million workers in the United States between 50 and 59 years of age have significant occupation-related hearing loss.¹²⁵ Noise can be defined as any unwanted sound, which can be further characterized by duration, time pattern (continuous, intermittent, or impulsive), frequency, and intensity. Although loud sounds from concerts and personal listening devices may not be classified as noise, they are included as noise for the purpose of the discussion. The intensity is measured in sound pressure levels (SPLs) and expressed in a logarithmic scale in decibels (dB). The intensity of a normal conversation is approximately 65 dB (Table 26–5).¹²⁵ The risk of noise-induced hearing loss is related to cumulative duration of exposure, intensity, and individual susceptibility.^{122,128,183} Much of the risk assessment of noise-induced hearing loss is inexact. Most authorities agree that sounds with maximal intensity below 75 to 80 dB will not cause hearing impairment, regardless of the duration of exposure.¹²² At higher intensity, the risk of hearing impairment increases with increased duration of exposure. Continued occupational exposure at 90 to 94 dB typically causes some high-frequency hearing loss in approximately 10 years.^{2,128} Further exposure results in hearing loss in the lower-frequency range. The Occupational Safety and Health Administration (OSHA) established guidelines for permissible occupational noise exposure based on an analysis of the average intensity and duration of exposure (Table 26–6).^{2,183}

TABLE 26–5. Typical Sound Levels on the Decibel Scale

<i>Sound</i>	<i>Decibels</i>
Weakest sound that humans can detect	10
Quiet bedroom, soft whisper	20
Broadcast studio	25–30
Insulated lounge	50
Normal conversation	65
Television-audio	70
Vacuum cleaner	80
Machine press, subway car (35 mph)	95
Spray painting, snowmobile	105
Power saw	110
Maximum volume of MP3 players	100–115
Loud rock concert, car horn	115
Armored personnel carrier; ear pain begins	120
Jet plane engine, gunshot	145
Highest sound level that can occur	194

115	≤0.25

^aDecibels using the A-scale filter.

The pathophysiology of noise-induced hearing impairment is related to an excessive energy impact on the cochlea, but the exact biochemical changes are unclear. Apoptotic death of the hair cells can be demonstrated and inhibition of apoptosis pathways mitigates noise-induced toxicity in animal models. A limited exposure to excessive noise results in a temporary hearing impairment or temporary threshold shift with a duration of hours to weeks. However, prolonged exposure results in a permanent threshold shift or hearing impairment.^{3,54,183} Initially, outer hair cells are lost, but more significant exposures result in damage to both inner and outer hair cells and all supporting structures in the organ of Corti. Cochlear nerve fibers degenerate after hair cell damage.^{54,183} The section of the cochlea most at risk from loud noises is at the region of 9 to 13 mm (total length is 32 mm).¹¹² This region is responsible for hearing at the range of 3000 to 6000 kHz, corresponding to the typical noise-induced hearing loss pattern.

Much of the clinical assessment and monitoring of noise-induced hearing loss is based on pure tone hearing loss, demonstrating an audiometric deficit at 3000 to 6000 kHz.^{125,128,183} Although human speech is composed mainly of low frequency sounds, the ability to perceive the higher frequency sounds is extremely important in speech recognition. For this reason, the major impairment in patients with noise-induced hearing loss is an inability to discriminate speech, particularly from background noise.^{2,42} Currently, the science of the investigation of speech discrimination is limited with extensive areas for research.

Blast injury to the ear results from exposure of extremely short duration, but very high-intensity sound waves, usually greater than 140 dB. Military personnel are particularly at risk.^{30,129,175,178} Hearing loss from blast injury may be related to rupture of the tympanic membrane, disruption of the ossicles, temporary cochlear dysfunction, and permanent cochlear dysfunction from labyrinthine fistulae and basilar membrane rupture.²⁸ When a large tympanic membrane rupture or disruption of the ossicles occurs, surgical intervention may be required to treat hearing impairment.²⁸

Prevention of any type of noise-induced hearing loss remains the best solution. Various hearing-protection devices are available if the noise exposure cannot be reduced. Better monitoring and more longitudinal studies are required on noise-induced hearing loss. Exposures to xenobiotics that can impair hearing may have synergistic effects with noise-induced hearing loss.^{95,97} These factors should be considered when noise exposure is evaluated. Furthermore, noise exposure is not limited to the workplace. Significant noise exposure may occur at home or from leisure activities, such as the use of power tools, loud music, and ambient exposure.^{15,38,74,128} The impact of noise exposure outside of the workplace has only recently attracted the attention of investigators.

Tinnitus

Tinnitus is the sensation of sound not resulting from mechanoacoustic or electric signals. Virtually all humans experience tinnitus during their lives. The exact mechanism or mechanisms resulting in tinnitus are largely unknown.¹⁵² Tinnitus may or may not be associated with hearing loss. Several theories are proposed, but none is completely satisfactory. Tinnitus may result from spontaneous neurologic discharges when the hair cells or cochlear nerve is injured. Altered sound perception may result from local or central effects when feedback mechanisms are interrupted.^{45,51,88,111} Severing the cochlear nerve terminates tinnitus in less than half of affected patients, suggesting important central mechanisms.¹⁰ Furthermore, certain etiologies of tinnitus, such as migraine headache and temporal lobe seizures, do not affect hearing directly. N-methyl-D-aspartate (NMDA) glutamate receptor activation (and enhanced cochlear signal transmission) is implicated as a mechanism for tinnitus in animal models; NMDA receptor activation may result from cyclooxygenase inhibition or neurologic injuries.^{76,131} Xenobiotics, including salicylate, may cause hair cell dysfunction and may modify neurotransmission centrally in both the cochlear nucleus and the inferior colliculus.^{65,182} Although the probable sites involved in tinnitus may be classified as peripheral (external ear, middle ear, or cochlear {CN VIII}), central, or extra-auditory (vascular, nasopharyngeal), some etiologies may affect peripheral and central sites, and many etiologies remain unknown.^{35,51,111}

Numerous xenobiotics are associated with tinnitus (Table 26–7), but the incidence is probably low and the implied relationships are usually supported only by case reports.^{33,157,158} Tinnitus may or may not be associated with transient or permanent hearing loss. It is probable that the xenobiotics associated with hearing loss affect cochlear function, while those that produce tinnitus without hearing loss probably act on signal transmission at the cochlea in the CNS. Xenobiotics that frequently produce tinnitus include streptomycin, neomycin, indomethacin, doxycycline, ethacrynic acid, furosemide, heavy metals, and high doses of caffeine.^{69,157,158} Only a few xenobiotics, such as quinine and salicylates, consistently cause tinnitus at toxic doses.^{16,51} These two xenobiotics also serve as examples of how the presence of tinnitus may be an indicator of drug toxicity.

TABLE 26–7. Xenobiotics That Cause Tinnitus

β-Adrenergic antagonists
Anticonvulsants: carbamazepine
Antidepressants: cyclic antidepressants, amoxapine, lithium, trancylcypromine
Antifungals: amphotericin B
Antihistamines
Antimicrobials: aminoglycosides, vancomycin, dapson, tetracyclines, sulpha drugs, metronidazole, thiabendazole, clindamycin

Antiparasitics: chloroquine, hydroxychloroquine

Antipsychotics: haloperidol, molindone

Bromates

Chemotherapeutics: cisplatin, nitrogen mustard, 6-aminonicotinamide, methotrexate, vinblastine

Cinchona alkaloids: quinine, quinidine

Diuretics: furosemide, ethacrynic acid, bumetanide

Hydrocarbons: benzene

Local anesthetics: mepivacaine, bupivacaine, lidocaine

Nonsteroidal antiinflammatory drugs

Oral contraceptives

Salicylates

Sympathomimetics: caffeine, theophylline, metaproterenol, albuterol, methylphenidate

Tinnitus associated with salicylates usually begins when serum concentrations are in the high therapeutic or low toxic range of approximately 20 to 40 mg/dL.¹¹⁷ Membrane permeability changes cause a loss of outer hair cell turgor in the organ of Corti which may impair acoustic emissions, explaining tinnitus to some extent.^{131,132,135} NMDA-receptor activation from cyclooxygenase inhibition may also cause tinnitus.¹³¹ Before the wide availability of serum salicylate measurements, physicians treating gout or rheumatoid arthritis often titrated the salicylate dosage until tinnitus developed.¹¹⁷ Tinnitus and other signs and symptoms of salicylism ([Chap. 39](#)) should be sufficient for physicians to diagnose salicylate toxicity before serum salicylate concentrations are available. However, tinnitus may not be evident in patients with hearing impairment despite significantly elevated salicylate concentrations.¹¹⁷ The classic constellation of symptoms of quinine and salicylate toxicity, called cinchonism, includes nausea, vomiting, tinnitus, and visual disturbances.^{4,26,120} Because serum quinine concentrations are not readily available, symptoms of quinine toxicity define the clinical diagnosis ([Chap. 59](#)).¹⁶⁸

SUMMARY

- Numerous xenobiotics commonly affect the sense of smell, taste, and hearing, thus causing significant morbidity.
- Some of the events may be predictable, whereas others will require monitoring and appropriate testing.
- Current knowledge about the pathophysiology of xenobiotics and these special organs at the molecular level is rapidly expanding.
- Although no definitive antidote is available for the prevention or treatment of xenobiotic-induced ototoxicity in humans, substantial progress has been achieved in both in vitro and in vivo animal models.

27 PSYCHIATRIC PRINCIPLES

Erin A. Zerbo and Andrea M. Kondracke

Psychiatric problems may be the cause or the effect of many toxicologic presentations. Suicide attempts and aggressive behaviors are commonly associated with toxicity and can be uniquely difficult to assess and manage. Patient behaviors are often viewed dichotomously as either totally intentional and deliberate or totally “out of control” and irrational. The truth is usually more complex, with some aspects occurring within the awareness and control of the patient and other aspects either unknown or overwhelming to the patient. Neuropsychological conceptions of “behavioral disinhibition” as a baseline personality trait that is relatively fixed are complementary to presumed organic etiologies of disinhibition such as intoxication or brain injury; in the latter cases, frontal lobe dysfunction is directly implicated. Yet more subtle frontal lobe dysfunction is likely occurring in many patients without such a direct neurological insult: patients with psychosis or mania, personality disorders, attention-deficit/hyperactivity disorder, or even agitation in the context of psychological distress. A patient’s innate capacity for self-restraint can vary widely, and some will present with behavioral disturbances much more readily than others.¹¹²

Issues of capacity often arise with intoxicated or impaired patients, and the basic approach to capacity assessment will be covered. “Medical clearance” is usually requested prior to a patient’s transfer to psychiatric care, yet this has proven to be a rather vague concept that lacks a standard protocol; however, there are practice guidelines addressing this issue, which will be discussed. This chapter also explores the topics of suicide/self-harm and violence to enable the physician to adopt the appropriate role of both diagnostician and medical decision-maker. Finally, substance use disorders (SUDs) will be addressed, given that they are problematic in the emergency setting and highly comorbid with suicidality and violence.

CAPACITY

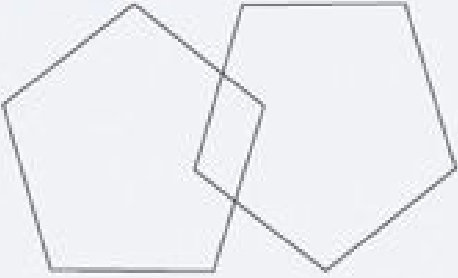

Physicians are legally and ethically required to obtain informed consent before treating a patient to allow the patient to make a voluntary choice about his or her care. However, if a patient is cognitively impaired, the physician must make a careful assessment of capacity and proceed as medically necessary should the patient be found to lack capacity. It does not matter whether the cognitive impairment is due to psychiatric illness, medical illness, or a transient xenobiotic-induced delirium; if the patient is unable to make a logical and rational decision stemming from his or her personal value system, the physician can override the patient’s autonomy to provide necessary care.⁷ Traditionally, the term “competence” denotes a legal status determined by a court of law, whereas “capacity” is assessed by a physician in a clinical setting. The distinction between these terms has become blurred in both the medical and legal literature, but it is a helpful framework nonetheless.⁷

It is important to note that capacity assessments occur at a specific moment in time regarding a specific medical decision. The assessment is not a “global” determination that persists throughout the hospitalization or even the length of an emergency department (ED) visit, but rather a temporary determination that requires reassessment as factors change. Capacity may fluctuate with a change in the patient’s mental status, medical or psychiatric condition, the time of day, amount of pain, level of anxiety, perceived support, recent medication administration or in the context of withdrawal from a xenobiotic.

While disease status cannot be used to determine capacity, some correlations have been noted in the literature. Fifty percent of patients with schizophrenia who are hospitalized with an acute psychotic episode will not have capacity; more than 50% of patients with mild-to-moderate dementia will also lack capacity, and this increases to 100% with severe dementia. If the Mini-Mental State Exam (MMSE) (Table 27–1) score is lower than 19 out of 30 possible points, it is highly unlikely the patient will have capacity.⁵¹ Most patients with mild-to-moderate depression do not have impaired capacity, yet 20% to 25% of hospitalized patients admitted with severe depression do lack capacity.⁷ Nonetheless, capacity should always be carefully assessed, since active psychiatric symptoms or long-standing cognitive impairment do not invariably lead to a lack of capacity.

TABLE 27–1. The Mini-Mental State Exam

Patient _____	Examiner _____	Date _____
---------------	----------------	------------

Maximum	Score	
		Orientation
5	()	What is the (year) (season) (date) (day) (month)?
5	()	Where are we (state) (country) (town) (hospital) (floor)?
		Registration
3	()	Name three objects: one second to say each. Then ask the patient all three after you have said them. Give one point for each correct answer. Then repeat them until he/she learns all three. Count trials and record. Trials _____
		Attention and Calculation
5	()	Serial "7's". One point for each correct answer. Stop after five answers. Alternatively, spell "world" backward.
		Recall
3	()	Ask for the three objects repeated above. Give one point for each correct answer.
		Language
2	()	Name a pencil and watch.
1	()	Repeat the following "No ifs, ands, or buts"
3	()	Follow a three-stage command: "Take a paper in your hand, fold it in half, and put it on the floor."
1	()	Read and obey the following: CLOSE YOUR EYES
1	()	Write a sentence.
1	()	Copy the design shown.

Reproduced with permission from Folstein MF, Folstein SE, McHugh PR: Mini-mental state". A practical method for grading the cognitive state of patients for the clinician. *J Psychiatr Res.* 1975 Nov;12(3):189-98.

Depriving a patient of his decision-making rights is a serious infringement on liberty. While physicians are implicitly assessing patients' capacity on a regular basis, they often have little formal training and may not have a systematic approach. This limitation leads to difficulty determining capacity in murky ethical situations, confusing clinical scenarios or when a patient is making "bad" decisions (such as refusing treatment of clear benefit or refusing life-sustaining measures). Patients refusing treatment in the setting of a recent suicide attempt, such as refusing an antidote for a potentially lethal ingestion, is one frequently encountered scenario (see Suicide).

Intricacies of capacity assessment may be dictated by individual jurisdiction and it is important to know the laws in the area within which you practice. For example, some states require two separate assessments by physicians that are separated in time. The assessment should be done by a physician familiar with the procedure and able to discuss risks and benefits, and should include assessment of the patient's mental status, educational level, and any cultural factors that may be relevant. A well-researched scale for determining decisional capacity is the MacArthur Competence Assessment Tool for Treatment (MacCAT-T), a semi-structured interview that requires 15 to 20 minutes to administer and is designed for use in a clinical setting (Table 27-2).⁵⁹

Interview Process (15–20 minutes):

- Clinician discloses patient’s disorder, recommended treatment, risks, benefits, and alternative treatments
- Patient expresses a treatment choice and explains how the choice was made

Questions embedded in the interview process assess patient’s abilities in 3 areas:

1. Understanding

- Ask the patient to paraphrase what has been disclosed about the disorder, the recommended treatment, and the risks/benefits.
- If a patient demonstrates poor understanding, redisclose the information and reassess (if a patient wasn’t paying attention or found the concepts unfamiliar, his or her understanding should improve with redisclosure).

2. Appreciation

- Does the patient acknowledge that the information applies to him or her? That treatment might have at least some benefit?
- A reasonable difference of opinion is permissible; however, if a patient’s opinion is derived from delusional or distorted perceptions, these patients are lacking appreciation.

3. Reasoning

- Has the patient expressed a preference? What are his or her explanations for making that choice? Does he or she mention any consequences of treatment alternatives, how alternatives compare, or any thoughts about consequences besides those offered in the disclosure? Does the patient’s final choice follow logically from the explanation?
- If the patient is not able to logically explain how he/she arrived at a choice, or is inconsistent in the choice, this indicates a failure of reasoning.

Data from Grisso T, Appelbaum PS, Hill-Fotouhi C: The MacCAT-T: a clinical tool to assess patients’ capacities to make treatment decisions. *Psychiatr Serv.* 1997;Nov;48(11):1415–1419.

The general legal standard for capacity requires assessment of four basic skills, which should be clearly documented:⁷

1. Communicate a Choice. The patient must be able to indicate a choice, and to be consistent long enough for the choice to be implemented. A patient may alter the decision over time or with new information, but repeated reversals of a decision suggest a lack of capacity. Difficulties in this first measure can occur in patients who have a high degree of ambivalence, patients with poor short-term memory or a thought disorder, or patients who are unconscious or delirious.

2. Understand Relevant Information. As a first step, the physician should provide all the relevant information in a patient’s primary language and in an understandable manner. In addition to describing the medical condition, the proposed intervention(s) and the risks and benefits, the physician should be certain to address the possibility of “doing nothing” and the associated risks/benefits with this decision.

Physicians often feel that this step is the key to capacity assessment, and that if a patient can verbally repeat the details of the procedure and the risks/benefits/alternatives that capacity has been established. However, the assessment is more nuanced than this. The patient should be able to understand and manipulate the information independently, which can be demonstrated by asking the patient to paraphrase the physician’s explanations rather than repeat verbatim. The patient should understand that probabilities, not certainties, are being discussed, and that he or she has an autonomous role as a decision-maker. Difficulties in this domain can arise from deficits in attention, intelligence, or memory.

3. Appreciate the Situation and Its Consequences. The patient may be able to comprehend the relevant information, yet it is important to ensure that the patient is also able to apply the facts to the individual’s particular situation. The medical condition in question must be acknowledged, and the individual must demonstrate awareness that the risk and benefits being discussed apply to this unique personal situation. Courts have clarified that patients who do not acknowledge their illness do not have capacity. Difficulties in this area often arise from pathologic denial, mistrust of the motivation of the physician, cognitive or affective impairment, or delusional thinking.

4. Reason about Treatment Options. This final step describes the patient’s ability to comprehend and incorporate the relevant information as applied to this particular situation in order to logically reach a decision about his or her treatment. The physician should ask the patient to compare treatment options and consequences, and should inquire about how the choice was selected; the patient should be able to explain the reasoning involved and discuss the major factors considered. If a patient is unable or unwilling to explain the personal reasoning process, as sometimes can occur in the setting of anger or irritability, the capacity assessment is not complete and this suggests a lack of capacity until proven otherwise. Patients are allowed to make “unreasonable” choices, but they should be able to explain their reasoning process. Difficulties in this

domain often occur in patients with delirium, dementia, extreme phobia, panic, anxiety, psychosis, depression, or anger. Patients with SUDs might be experiencing withdrawal or intense craving and therefore demanding to leave and unwilling to participate in a discussion about their reasoning; addressing their withdrawal or cravings directly can often result in significant relief and rapid re-establishment of capacity.

Once a patient is deemed not to have capacity at a specific time to make a specific decision, the evaluation should proceed to determine the reason for this lack of capacity and the route through which it might be restored. Every effort should be made to assist in the restoration of patient capacity in order to protect autonomy. Individual state laws may mandate when court proceedings should be pursued, often depending on the level of invasiveness of a procedure: For example, a venipuncture is much less invasive than a surgical procedure, and would not require a special court order. However, for a procedure such as a limb amputation, the physician should likely pursue a court decision. In unclear circumstances, the physician can consult with the hospital's risk management department. Every effort to find an alternative decision-maker should be made. When there is no designated health care proxy and family members are not in agreement about the best treatment choice, most states have determined a specific hierarchy to determine which family member should make the decision.⁸

Complexities of Capacity Determination in Clinical Settings

Decisional capacity is often part of a larger question about how to proceed with treatment for a particular patient. If a patient is found to lack capacity, ethical questions arise about the appropriateness and practicality of imposing treatment; such as the consideration of sedating a patient to obtain a blood sample. Sedating a patient has its own inherent risks, and psychological distress to the patient cannot be discounted. In these situations it is often helpful to have a discussion involving the psychiatrist, and a general consensus can usually be reached about the balance of costs and benefits to proceeding with treatment against a patient's will. Life-threatening refusal of treatment is always clear, but the physician often quickly encounters a "gray area" in which the medical necessity of a treatment is less urgent. The physician has a responsibility to petition the court for invasive procedures such as surgery if the patient's medical condition is stable enough to allow this, but if the situation becomes urgent, the physician can proceed without involving the court. In these cases, it is often helpful to have a team approach involving psychiatry, risk management, and a bioethics consultation if available.

Another important concept is the sliding scale of capacity, which has been supported by both expert consensus guidelines and the legal system. This "sliding scale" concept indicates that the threshold for deeming a patient to lack capacity changes depending upon the seriousness of the consequences. For example, a patient refusing treatment in a life- or limb-threatening situation would be held to a higher standard of capacity than for a patient refusing a venipuncture. A life-threatening situation requires the patient to clearly demonstrate a thorough understanding of the relevant information, its application to the situation and the individual's reasoning process in order to be deemed to have capacity. On the other hand, even if a patient doesn't technically have capacity to refuse a blood draw, if it is not medically necessary at that moment, the patient might be allowed to refuse. This philosophy stems in part from our conception of a modern democracy in the United States, in which the vast majority of persons are considered capable to make their own decisions. We would like to preserve this autonomy when it is not dangerous to the patient's health.⁷

MEDICAL CLEARANCE

Not all patients who present with psychiatric symptoms have mental illness. Intoxication, withdrawal syndromes, medical illness, and organic brain disease can often mimic mental illness. Patients with behavioral disturbances present unique challenges to diagnostic assessment given that they are unlikely to be cooperative and it can be difficult to achieve a comprehensive medical history. Emergency physicians are usually asked to "medically clear" the patient before transfer to psychiatric care, yet there is no standard process for this.

In general, psychiatrists request that ED physicians: (1) determine if presenting symptoms are caused or exacerbated by a medical illness, (2) assess and treat any acute medical issue necessitating urgent or emergent intervention, and (3) determine if the patient's symptoms are primarily related to a xenobiotic, which would preclude an accurate psychiatric evaluation.⁸⁰ Obvious signs of need for further evaluation include abnormal vital signs, delirium, altered cognition, or an abnormal physical examination. Four other groups are identified as high risk for medical instability: the elderly, patients with substance abuse, patients without any prior psychiatric history, and those with preexisting medical disorders or current medical complaints.⁵⁸

While routine laboratory testing is often requested by the psychiatrist for medical clearance, a number of studies demonstrate that selective testing based on history and physical examination is probably the correct strategy. There is a strong consensus among ED physicians that routine laboratory testing is unnecessary, and without any clinical suspicion, the probability of false positive laboratory results begins to outweigh true positives.^{16,42} The American College of Emergency Physicians (ACEP) provides a level B recommendation that diagnostic evaluation be directed by the history and physical

examination, and that routine laboratory testing is low yield and not necessary as part of the ED assessment.⁸⁰

ACEP also provides a level C recommendation against routine urine toxicology testing and blood alcohol concentrations in alert, awake and cooperative patients, and specifies that transfer to psychiatric care should not be delayed to await collection of samples for toxicologic analysis.⁸⁰ However, from the psychiatrist's perspective, this testing is time-sensitive and can change psychiatric management and disposition considerably. If the emergency physician knows the patient will be transferred for psychiatric care and suspects substance abuse, it would be helpful to obtain toxicologic results as early as possible in the hospital course, but also can be done after transfer if necessary.

A final issue is if the patient is intoxicated with alcohol. At what point is it appropriate to "medically clear" the patient for a psychiatric evaluation? There are no evidence-based data to support that patients regain decision-making capacity at a particular blood alcohol concentration. Depending upon tolerance, cognition can vary widely, and patients often develop ethanol withdrawal while consequential blood alcohol concentrations persist.³⁹ Therefore, ACEP provides a level C recommendation that the patient's cognitive abilities should be the basis on which the psychiatric assessment is begun, and a period of observation can be used to see if psychiatric symptoms resolve with intoxication and a psychiatric assessment is no longer needed.⁸⁰

SUICIDE AND SELF-INJURIOUS BEHAVIOR

Suicide was the tenth leading cause of death in the United States, accounting for 38,364 deaths in 2010.²⁸ It was the third leading cause of death among 15 to 24 year olds, and accounts for 20% of deaths in this age group annually. Although suicide may be attempted or accomplished in a variety of settings and by a variety of means, it is most typically associated with psychiatric disorders and/or substance abuse, especially ethanol, and is frequently accomplished with psychoactive xenobiotics alone or in combination.

Terminology

The terms and definitions of suicide and suicidal behaviors used in this chapter have been outlined in several reports on the subject. The term suicide refers to self-inflicted death with either explicit or implicit evidence that the person intended to die. The term suicidal ideation refers to thoughts of serving as the agent of one's own death, and suicidal ideation may vary in seriousness depending on the degree of suicidal intent and the specificity of suicide plans. Suicidal intent refers to the subjective expectation and desire for a self-destructive act to end in death, and suicidal plan refers to the formulation of a specific method through which one intends to die.

A suicide attempt is a self-injurious behavior with a nonfatal outcome accompanied by either explicit or implicit evidence that the person intended to die. The related term suicide gesture generally refers to an attempt which is not felt to be medically serious, and often implies that the patient is making a "cry for help" rather than truly attempting to die; such a gesture can still result in death, even if unintentional. As defined in the literature, "serious" suicide attempts meet one of the following criteria: (1) treatment in a specialized unit (such as an intensive care unit), (2) surgery under general anesthesia, (3) medical treatment beyond gastric lavage, activated charcoal, or routine neurologic observation, (4) method with high risk of fatality (such as hanging or firearm), or (5) hospital admission longer than 24 hours.¹²

Self-harm or self-injurious behavior refers to the self-infliction of painful, destructive, or injurious acts without the intent to die. An example is the superficial cutting that occurs in a patient with a borderline personality disorder, which is actually a coping mechanism that provides psychological relief; one hypothesis is that relief is mediated by the endogenous release of opioids.⁹⁹ However, the distinction of suicidal and "parasuicidal" behaviors such as these is outside of the scope of the medical toxicologist, and a mental health professional should be consulted to help make such a distinction.

Finally, the lethality of suicidal behavior is an objective measure of the "danger to life" associated with self-injurious behavior. It is important to note that objective lethality may be distinct from subjective lethality. This occurs when a patient does not truly expect a behavior to be as medically dangerous as it turns out to be, or vice versa. For example, a patient may not be aware that an acetaminophen (APAP) overdose can be fatal, believing that its status as a "nonprescription" medication indicates that it is less likely to be fatal in overdose than a prescribed medication.

Epidemiology

Suicidal thoughts and behaviors are common. An estimated 8.3 million adults in the United States reported having suicidal thoughts in 2008, and approximately 1 million actually made an attempt that year.³⁵ Studies have consistently found that self-poisoning accounts for more than 70% of all serious suicide attempts.⁸³ While there is reportedly one suicide completion for every 25 attempts, this ratio dramatically decreases for adolescents and young adults. Among 15 to 24 year-olds, there are approximately 100 to 200 attempts for every completed suicide.⁴³

Ninety percent of suicide completers and attempters meet criteria for a diagnosable psychiatric illness, 70% have mood disorders, and 30% have alcohol abuse or dependence.⁶⁴ On average, one-third of suicide decedents test positive for

alcohol, and 65% of them have a blood alcohol concentration higher than 80 mg/dL.⁷³ Many individuals who complete suicide do so on the first attempt. Although a prior suicide attempt is still the strongest predictor of a future completed suicide, only about one in 10 attempters is successful.^{62,88} Multiple attempters also appear to have higher risk than those who make a single attempt.^{57,103} Medically serious attempts, defined as involving treatment in a specialized unit, surgery, or medical treatment beyond stomach evacuation, may be a more robust marker of risk. Those who make serious attempts tend to share with completers a higher rate of serious mental illness such as schizophrenia, bipolar disorder, or severe major depressive disorder.¹²

Suicidal or self-injurious patients are often encountered in EDs. Approximately 70% of all self-inflicted, nonfatal injuries seen in an ED are the result of a suicide attempt, and an ED visit for self-harm is predictive of a completed suicide in the future.^{23,94} Anywhere from 1% to 2.7% will commit suicide within the next year or two.^{65,94} The average annual number of ED visits for attempted suicide and self-injury has nearly doubled over the last 15 years: from 244,000 in the early 1990s to 538,000 in the mid-2000s.¹⁰⁷ Self-poisoning was the most common method at 68%, followed by cutting or piercing at 20%.⁴⁴ Increases occurred in all major demographic groups: males, females, Caucasians and African Americans. ED visits were most common among those aged 15 to 19 years.¹⁰⁷

Although the prevalence of suicide and suicidal behaviors shows significant overlap, one notable area of difference is the consistent pattern of higher rates of suicide attempts among women and of completed suicides among men.^{22,26} Men account for 80% of completed U.S. suicides at a rate highest among men greater than 75 years of age. Men are more likely to use a firearm, at rate of 57% versus 34% in women; some authors suggest this difference in method leads to the disparity in completed suicide rates as compared with women, who are more likely to self-poison.^{28,73}

Self-Poisonings

According to the National Electronic Injury Surveillance System, which surveys a select number of nationally representative hospitals, an estimated 170,000 people were treated in ED for poisonings in 2000. Sixty percent of these were classified as “probable” suicide attempts, 10% were “possible” suicide attempts, and the intent for the remaining 30% was “unclear/unknown.” Women were more likely to self-poison than men (72% vs 55%), and the highest rate of self-inflicted injury occurred in adolescents aged 15 to 19 years (especially women), followed by young adults aged 20 to 24 years. Ethnically, rates were highest among non-Hispanic Caucasians of both sexes.²³

In the 16 states participating in the National Violent Death Reporting System in 2009, self-poisoning was the third leading method of suicide (following firearms and hanging/suffocation).⁷² Detailed data from 2005 to 2007 indicates that 75% of individuals poisoned themselves with a substance (either illicit or licit, including alcohol) as opposed to other types of poison such as carbon monoxide. Seventy percent of individuals ingested just one “drug type,” defined as prescription drugs versus nonprescription drugs versus alcohol/illicit drugs. Out of poisoning deaths due to a single “drug type,” 80% were due to prescription drugs such as opioids, benzodiazepines, or antidepressants, and 10% were due to nonprescription drugs such as APAP. When individuals consumed more than one “drug type,” 45% involved alcohol or illicit drugs as part of the combination.^{25,28,72} It was estimated that for every self-poisoning death in the United States, there were 33 intentional overdoses reported to poison centers ([Chap. 136](#)), of which two ultimately went untreated.²⁹

There is a large body of literature about self-poisoning in the United Kingdom, and their data indicate proportionally higher death rates among poisonings with tricyclic antidepressants (TCAs) versus selective serotonin reuptake inhibitors (SSRIs), which is not surprising given the cardiac toxicity of TCAs. Venlafaxine, a serotonin-norepinephrine reuptake inhibitor (SNRI), is more toxic in overdose than SSRIs. Poisoning deaths with atypical antipsychotics such as clozapine, olanzapine, and quetiapine were increasing, especially as of the early 2000s.⁴⁹

Given that the act of suicide is a statistically rare event in the overall population, it is virtually impossible to predict who will actually commit suicide. Therefore, it is critical to identify risk factors that increase the likelihood that any individual might attempt suicide, and to identify risk factors that are modifiable ([Tables 27–3 and 27–4](#)). The identification of modifiable risk factors provides opportunities for interventions that may decrease suicide risk. Additionally, there are protective factors that mitigate the risk for suicide, and it is important to assess for the presence or absence of these factors in determining the overall risk for suicide in a patient.

TABLE 27–3. Factors Associated with an Increased Risk for Suicide

<i>Psychiatric Risk Factors</i>	<i>Neurological and Medical Factors</i>	<i>Sociodemographic Factors</i>	<i>Genetic and Familial Factors</i>
Major depressive disorder	Diseases of the nervous system	Access to firearms	Family history of suicide (particularly in first-degree relatives)
Bipolar disorder	Multiple sclerosis	Male sex (suicide completion)	Family history of mental illness, including substance use disorders
Schizophrenia	Huntington disease	Female sex (suicide attempts)	
Alcohol use disorder	Brain and spinal cord injury	Widowed, divorced, or single marital status, particularly among elderly men	
Other substance use disorders	Seizure disorders	Elderly age group	
Alcohol intoxication	Malignant neoplasms	Adolescent and young adult age groups	
Personality disorders	HIV/AIDS	Gay, lesbian, or bisexual orientation	
Bulimia or anorexia nervosa	Chronic pain syndromes	Recent lack of social support (including living alone)	
Post-traumatic stress disorder	Caucasian race	Unemployment	
Helplessness	Functional impairment	Decrease in socioeconomic status	
Hopelessness	Low concentration of serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid—(Research)	Domestic partner violence	
Impulsivity		Recent stressful life event	
Aggression, including violence against others		Childhood sexual abuse	
Agitation		Childhood physical abuse	
Factors related to current or past suicidal behavior:			
Prior suicide attempts			
Suicidal ideation			
Suicidal plans			
Suicidal intent and lethality

PSYCHIATRIC MANAGEMENT OF SELF-POISONING

Table 27–5 depicts a case of suspected self-poisoning from the starting point of prehospital care through the completion of a comprehensive assessment and treatment planning.

TABLE 27–5. Case Presentation: Suspected Self-Poisoning

	<i>Case</i>		<i>Evolution</i>		<i>Disposition</i>
Patient course	Patient found in the community unresponsive	Patient monitored in the emergency department; vital signs stable; still unresponsive	Patient lethargic but cooperative; answers simple questions	Patient fully awake and alert	Evaluation complete
Treatment course	Prehospital	Triage medical assessment	Observation and monitoring	Formal psychiatric evaluation	Treatment planning
Physician course	Patient identification Search for prescription drugs, drug paraphernalia Assessment of cardiac and respiratory function	Orogastric lavage (?) Activated charcoal (?) Diagnostic testing (blood studies, electrocardiography, urine toxicology) Contact collateral sources for history Prior records	Focused psychiatric assessment: elopement aggressive behavior decisional capacity addressing confidentiality immediate suicide risk	Comprehensive psychiatric assessment: diagnostic interviewing risk factors future risk	Treatments: medication hospitalization substance abuse counseling crisis intervention family therapy

Initial Psychiatric Management

In any case of suspected self-poisoning, a thorough psychiatric assessment is warranted. It can be helpful to call a psychiatric consult immediately after medical stabilization, even if the patient is unable to communicate, since important information such as pill bottles, ambulance reports, and the ability to call the patient's family and outside providers may be lost if the consult is delayed. Although not required for an ED assessment unless clinically indicated, it should be helpful for the psychiatrist if urine toxicology and blood alcohol concentration is obtained as early as possible.

An early, focused assessment is necessary to ascertain elopement risk and decisional capacity. Subacute residual central nervous system (CNS) effects of ingestions, such as confusion, fatigue, and fear, can dispose patients to wander or elope. The patient should be searched for weapons, pills, and other potentially toxic materials to prevent additional self-harm or ingestion in the hospital. Given that the patient's intentions remain unclear at this point, the question of unintentional versus intentional exposure to a xenobiotic cannot be completely resolved. For this reason, a high level of supervision should be maintained, and a patient should not be allowed to leave or be left unattended until an adequate assessment of the patient's mental status is completed. Depending on the architecture and organization of the ED and its personnel, it may be sufficient to place the patient in an open area in the direct line of sight of the medical staff. If such an arrangement is not possible, or if the patient is agitated and disruptive, it may be necessary to separate the patient from the general population. Under these circumstances, an individual aide should be assigned to observe the patient on a one-to-one basis. Safe physical and/or chemical restraints may be necessary to prevent further injury to both the patient and the staff.

At a relatively early point in the patient's course, when the patient can be cooperative, a more detailed psychiatric assessment is critical to address specific clinical concerns. Both history-taking and collateral contacts can help to establish the patient's preingestion mental status and baseline, as it may be difficult in an initial, time-limited assessment to differentiate a xenobiotic-induced delirium from mental illness and therefore ensure that any delirium has fully resolved. The determination that the patient is stable is not solely established on the basis of blood concentrations of a xenobiotic or ancillary medical tests, but rather when the emergency physician or medical toxicologist with an understanding of toxicokinetics and toxicodynamics deems it appropriate.⁶⁶ Although a thorough psychiatric examination is not possible until an altered mental status has cleared, it is reasonable to have the psychiatrist involved earlier for the above-mentioned reasons.

The physician should not unequivocally attribute altered mental status to poisoning or toxicity until the signs of altered consciousness have resolved and cognitive functions have returned to normal. Until that time, other toxic-metabolic and structural conditions that might coexist with, or masquerade as, toxicity cannot be excluded. If the patient's cognitive functioning is impaired by xenobiotics, then critical historical details may be unreliable.³³ It should be understood that much of what the patient reports may be ephemeral, caused by the predictable temporary and reversible effects on mood of these xenobiotics.¹⁴ However, any patient utterances about intended overdose or self-harm should be documented in the record, since it is important information to consider if the patient becomes guarded and evasive after returning to baseline mental status.

In addition to routine laboratory studies, such as complete blood count, electrolytes, renal function, and liver function tests, psychiatrists usually request thyroid function tests, B12, folate, HIV testing, and syphilis immunoglobulin G antibody or RPR; abnormalities in these laboratory values can be associated with medical disorders producing psychiatric manifestations that would affect management and disposition. However, these laboratory tests have proven to be low yield when obtained routinely and without clinical suspicion, and are not necessary as part of the ED work-up.⁸⁰

Special Issues of Capacity in Suspected Self-Poisonings. Patients may request to be discharged, refuse care, or become

aggressive. Aggression may arise from lingering effects of ingestion or withdrawal, severe anxiety, fear, anger at the loss of autonomy, or the discomfort associated with unpleasant procedures.⁸⁶ Although patients may respond to verbal limit-setting and repeated explanations of their care, they may also require pharmacologic or physical restraint and involuntary treatment. Patients are not allowed to make poor health care decisions if their ability to weigh the risks and benefits of the proposed care is limited by cognitive deficits or mental illness. In the setting of toxicity, appropriate care may be provided under the doctrine of implied consent.

The emergency exception to the doctrine of informed consent may also apply in circumstances where self-injury is suspected. The emergency exception permits forcible detention, restraint, medication over objection, and necessary medical care until psychiatric assessment can be accomplished. This includes collecting information from collateral sources without the patient's consent. After the management of the immediate medical emergency and resolution of toxicity, suspected self-injury is sufficient evidence of impaired decisional capacity for the emergency physician to hold a patient for further psychiatric assessment. The emergency physician should document the patient's objections in the medical record and indicate the basis for the determination of diminished capacity.

After the intentionally self-poisoned patient is stabilized, there may be a need for a more thorough assessment of decisional capacity. Psychiatric consultation is appropriate at this stage to help document the degree of impairment, determine the etiology, and predict the likely course.

Immediate Risk of Self-Harm. After these safety considerations are addressed, the aim of the focused psychiatric assessment moves toward a determination of immediate suicide risk. This examination should answer the following questions: What is the patient's attitude toward lifesaving care? What are the patient's current wishes with regard to living or dying? What are the patient's thoughts about his or her rescue and likely recovery?

These questions can only be answered in the course of a frank discussion between the patient and the emergency physician. The physician should not be concerned about "provoking" further self-injurious impulses by having this vital discussion; many patients will be relieved that the health care professional is speaking directly about their distress.

Reliability and Confidentiality. Mention should be made here about the difficult issues of reliability and confidentiality with regard to gathering history. Evasiveness, lack of detail, inconsistency, and improbability may lead to an unreliable history. It is appropriate to confront the patient with the implausible aspects of this history and offer an opportunity for the patient to rethink the history. This is often successful, although subsequent reports are, of course, equally suspect.

The most important step from the standpoint of both clinical care and risk management is to locate other sources of information to clarify the patient's situation. A careful review of any previous medical and psychiatric records is critical. Any pattern to a patient's presentations such as increasing frequency, more aggravated behavior, or disheveled appearance should be noted.

Collateral contacts are another important source of information, although the level of involvement, sophistication, and reliability of the collateral contacts must also be taken into account. In the interest of providing necessary medical and psychiatric care for a patient in an emergent situation, the ED staff is legally permitted to solicit information from collateral contacts without the patient's consent. However, an effort should be made to obtain consent for any broader discussion of the patient's situation with family, friends, or other physicians. The patient may express concern about the ED staff contacting a family member or counselor. Any information to be imparted to third parties can be discussed in advance with the patient. The patient may restrict consent to receiving information only and may withhold consent to impart certain information. More caution is indicated in contacting an employer. Although disclosing information about the patient without the patient's consent is a breach of confidentiality, a physician may do so in the interest of protecting the patient ([Chap. 141](#)).⁵

Comprehensive Psychiatric Assessment

The goal of comprehensive psychiatric assessment is to: (1) characterize the nature of the attempt and any ongoing suicidal ideation that might be present, (2) explore risk factors for another suicide attempt, and (3) formulate a diagnostic impression. These three elements help to determine the level of risk and guide immediate treatment and disposition planning.¹¹⁰

The best understanding of suicide at this time is that it results from intrinsic vulnerability factors interacting with external circumstances, which can be termed the "stress vulnerability." Intrinsic vulnerability may be conferred by a variety of traits such as impulsivity or conditions such as depression, anxiety, low self-esteem, low self-efficacy, loneliness, and hopelessness. External factors include stressful life events, access to lethal means, and a host of other factors, positive and negative. Poor interpersonal problem-solving skills and a perceived lack of problem-solving ability also appear to increase risk.⁴⁰

Assessing Suicide Attempts and Suicidal Ideation. The core of the suicide risk assessment is a detailed discussion of the patient's suicide attempt and any ongoing suicidal thoughts and urges. It is important to establish rapport and introduce these topics in an appropriate context in order to improve the patient's candor. This evaluation requires significant time and skillful interviewing, for which there is no substitute. This approach will enhance both the therapeutic quality of the

interview and its reliability.

The clinician should explore the exact details of the attempt, including precipitating factors that may have begun days or weeks prior to the actual act. It is critical to determine the level of actual and intended lethality, along with the seriousness of the intent. Why did the patient make an attempt on that day or time? Understanding the patient's thought process can help to gauge the extent of impulsivity versus planning involved in the attempt. Signs of premeditation and planning are concerning, such as organizing one's affairs (giving away possessions, ensuring a will is updated) or writing goodbye letters (such as a phone call, internet posting or text message). It is crucial to determine if the patient expected to be found, and if any effort was made to notify someone about the impending attempt such as a phone call, internet posting, or text message. How was the patient discovered, and by whom? A patient who overdoses alone in a hotel room is very different from someone who overdoses in the bedroom while the family is at home. Current feelings about surviving should also be assessed: Is the patient relieved or upset to be alive? Is there currently active or passive suicidal ideation? How forthcoming does the patient appear to be when discussing this? Other important information includes prior suicide attempts and their lethality and circumstances, the frequency and duration of suicidal ideation in the past, prior psychiatric treatment, prior and current medication trials, and a detailed substance abuse history. Psychological factors such as reactivity to positive and negative external events and subjective distress are also important to explore. The social history should focus on interpersonal conflict, stressors within romantic or family relationships, and employment or financial concerns. Current support systems or lack thereof are important to note, as are feelings of isolation and abandonment, which can all be contributing factors.⁶⁷

The communication of suicidal ideas either directly or indirectly should not be misconstrued as a "cry for help" and hence evidence of lower risk. Communication is probably related to the degree of preoccupation with morbid thoughts and to personality characteristics that dispose individuals to revealing their thoughts to various degrees.⁷⁴ In psychological autopsy studies, approximately 50% to 70% of those who completed suicides gave some warning of their intention, and 30% to 40% disclosed a direct and specific intent to kill themselves.^{10,91}

Risk Factors for Suicide

The goal of assessing suicide risk factors is to identify factors that may increase or decrease the level of suicide risk in a particular patient, which will enable the clinician to develop a plan that addresses the modifiable factors. For example, hopelessness is one such modifiable risk factor, which would likely improve with time and treatment; when risk factors such as hopelessness can be modified on the inpatient psychiatric ward, an inpatient admission is warranted to help decrease the risk of suicide. Unfortunately, to date no study has ever identified one specific risk factor or set of risk factors as specifically predictive of suicide or other suicidal behavior; therefore, the assessment is ultimately based on clinical judgment. Despite the lack of such predictive factors for suicide, there is a large body of evidence on the multiple risk factors that contribute to suicide risk, and a growing body of evidence on protective factors (Tables 27–3 and 27–4). Knowledge of this evidence is critical to informing the clinical determination of suicide risk.

Risk factors are additive, with suicide risk increasing with the number of risk factors that are present, but certain risk factors interact synergistically to increase suicide risk. The combined risk of concomitant depression and alcohol intoxication may be greater than the sum of the risk associated with each in isolation. Certain risk factors, such as a recent suicide attempt associated with a high degree of lethality or the presence of a suicide note, should be considered serious on its own, regardless of whether other risk factors are present.³⁴

A number of avenues of inquiry suggest that violent suicide attempts are associated with a persistent deficiency in brain serotonin concentrations. Impulsive types of aggression and impulsive suicidal behavior have been linked to serotonergic dysfunction in prefrontal cortical regions of the brain.³⁶ This deficiency has been measured in the postmortem brains and spinal fluid of suicide victims and survivors of violent attempts as compared to nonviolent attempts and to other patients. Hopelessness has also received a significant amount of study as a potential predictor of suicide; unfortunately, it appears to have a high sensitivity but a low specificity.¹³ However, identifying hopelessness does provide for an intervention.

While much is known about the risk of suicide for various groups over time, little can be said with certainty about an individual patient at a particular point in time. The risk of suicide increases 50 to 100 times within the first 12 months after an episode of self-harm as compared to the general population risk. About one-half of all people who commit suicide have a history of self-harm, and this increases to 60% in juveniles.⁶ Unfortunately, there is no "typical" suicidal patient or clinically useful test or rating scale at this time. Albeit, while one investigator was able to prospectively identify almost all of those who ultimately died by suicide (97% sensitivity), the investigator overpredicted suicide by almost one-half (56% specificity).⁸⁸ However, there is also no patient in distress for whom the risk of suicide is so remote that it need not be considered.

Ultimately, most persons belonging to a high-risk group do not commit suicide, and some individuals with no apparent risk factors do. Many risk factors are not modifiable. This type of information, then, weighs most heavily in the assessment in the absence of other more specific data, early in the hospital course, or in the case of the uncooperative or hostile patient. The best foundation for treatment planning and clinical decision making is direct examination and clinical diagnosis.⁴³

Psychiatric Illness and Suicide. One major consideration in suicide risk assessment is the occurrence of severe mental illness. Suicide risk for individuals with severe mental illness is 20 to 40 times higher than it is for the general population.⁷⁵ Psychological autopsy studies, which focus historically on the decedent's intentions and mental state prior to death, have consistently revealed major psychiatric illness to be a factor in suicide and present in 93% of adult suicides.^{68,75,89,92} This is also true of those who make medically serious suicide attempts.^{13,68} In particular, prospective cohort studies and retrospective case control investigations have revealed clinical depression and bipolar disorder to dramatically increase suicide risk.^{60,74,109} For mood disorders, factors correlated with current suicidality include current depression, severe anxiety, anhedonia, panic, insomnia, ambivalence, and acute alcohol abuse.⁷⁴

After mood disorders, chronic alcoholism is the most commonly reported disorder and is present in approximately 20% of cases. Moreover, alcoholic patients who also experience episodes of depression are at a higher risk for suicide than patients who present with either disorder separately. There are considerable data that other types of substance use such as heroin, cocaine, or polydrug use also increase the risk of suicidality when psychiatric illness is present, and this seems to be especially true in depressive or dysphoric mood disorders (unipolar, bipolar II, and mixed types of bipolar I disorders).^{15,108} As a result, any assessment conducted on a patient with a substance use history must include an examination of symptoms of major depression or bipolar illness.^{47,111}

Patients with schizophrenia are at risk for suicide at rates comparable to major depression and are 20 times more likely to attempt suicide than the general population.¹⁰⁶ Approximately 50% of patients with schizophrenia will attempt suicide and 13% of schizophrenic patients will successfully complete suicide.^{17,106} Additionally, between 5% and 18% of patients with severe borderline personality disorder (especially those patients with comorbid depression) ultimately kill themselves.^{52,68,102}

The ability to treat psychiatric disorders such as mood disorders, schizophrenia, borderline personality disorder, and alcoholism suggests that most suicides are preventable. Indeed, a suicide prevention program designed for general practitioners in Sweden demonstrated evidence for prevention based on the detection and treatment of depression.⁹⁰ The Centers for Disease Control and Prevention reported that psychiatric problems in US EDs represented approximately 3% of mental illness visits, which is significantly lower than the national psychiatric rate of 20% to 28%.²⁷ This suggests that significant psychiatric underdiagnosis is occurring in the ED. Consequently, emergency physicians must enhance the comprehensive nature of their psychiatric screening to identify suicidality and concomitant mental disorders in patients presenting with self-injury.

Treatment

Following a comprehensive psychiatric assessment, the next step is deciding on treatment alternatives. Any patient who has made a suicide attempt must be considered to be at risk for another attempt and some further intervention is warranted. The risk of a subsequent lethal attempt is approximately 1% per year over the first 10 years. The risk is highest during the first year. Suicide is most commonly a symptom of an underlying disease process, so the goal is to diagnose and treat the underlying disease in the setting that is the least restrictive while also ensuring safety for the patient. The treatment alternatives available will depend on the psychiatric sophistication of staff available to the ED at any given time. This section describes the commonly used interventions in the ED; they can be employed singly or in combination.

Psychotropic medications can be used acutely in the treatment of severe anxiety or psychosis; however, in the case of antidepressants, several weeks are required for therapeutic effect, so their immediate use is not indicated in the ED. However, if the patient is to be discharged to the community with follow-up, it is reasonable for a psychiatrist to start an antidepressant in the ED setting. There are concerns about prescribing medications with relatively high potential for lethality in overdose, such as the TCAs and nonselective monoamine oxidase inhibitors, to persons who have recently attempted suicide. Medications for medical illnesses, such as insulin, should also be considered for risk of overdose. However, newer antidepressants, particularly the SSRIs, can be used as first-line drugs for treatment of most depressions and are relatively safe in overdose.

In 2007, the US Food and Drug Administration (FDA) ordered that all antidepressants should include a black box warning stating that there is an increased risk of suicidality in children, adolescents, and adults younger than 24 years of age. This risk was not increased in adults 25 to 64 years of age, and was actually decreased in adults older than 65 years of age. Further studies have confirmed this age-related difference.^{18,101} Proposed explanations include an ascertainment bias, activation and/or akathisia as an adverse event in the first few weeks, or increased energy resulting in increased ability to carry out suicidal plans. Nonetheless, the FDA and other authors emphasize that untreated depression also carries a risk of suicide, and treatment options should be carefully weighed with regard to their risks and benefits. Therefore, the initiation of antidepressant therapy by the nonpsychiatric physician is not recommended unless a tight linkage can be made between discharge and immediate (within days) aftercare by either a community outreach team or a crisis clinic.

Patients with depressive disorders may suffer from significant anxiety, as may patients with overwhelming situational stressors such as job loss, new financial hardship, bereavement, or divorce. The prescription of a short course (days to weeks) of a benzodiazepine may provide significant relief to the patient in crisis. Yet again, close psychiatric follow-up is

essential.

After the patient's immediate symptoms have been treated in the ED, the next treatment decision is determining the setting in which further treatment may safely be provided. Not all patients with suicidal ideation or even significant attempts necessarily require hospitalization, and there is still a substantial stigma attached to psychiatric hospitalization. In general, hospitalization should be used if less restrictive measures cannot ensure the patient's safety. If significant doubt exists about the safety of outpatient treatment, then the patient should be observed in the ED for further evaluation, admitted to a general hospital with close nursing supervision, or admitted to a psychiatric unit. "Holding beds," now available in some larger psychiatric EDs, are ideal for this purpose. Some localities may also have crisis outreach services that follow the patient after discharge from the ED and can provide appropriate monitoring and continuity of care.

Patients most likely to respond to interventions in the ED are individuals who have been stable, until recently but now, as a result of some external event, may find their way of life threatened. This acute change results in a painful state of anxiety and the mobilization of some combination of adaptive and maladaptive coping strategies. Finally, a second event, the precipitant, intensifies the anxiety to the point that the patient cannot tolerate the instability and is thrown into crisis. The patient then feels desperate and may be completely immobilized or vulnerable to various strong impulses including the impulse to run away, strike out at someone else, or kill him or herself. Reality testing is preserved, and no major psychiatric syndrome is present. The patient accurately perceives his or her situation, understands that the current reaction is a psychological problem, and is highly motivated to obtain help. The crisis may last for a matter of hours or weeks prior to the ED presentation and will ultimately resolve. Such patients respond well to crisis intervention and may actually undergo some positive development in the course of treatment.

By contrast, patients whose condition has been deteriorating for some time in the absence of significant stressors, and who appear on examination to be suffering from severe depressive symptoms, are unlikely to benefit rapidly from supportive techniques. If such patients present with suicidal ideation or attempts, it will be difficult, although not impossible, to manage them outside the hospital.

Outpatient settings have the advantage of maintaining the patient's functioning as much as possible. Work and childcare responsibilities, financial obligations, and social relationships are not disrupted. Unnecessary regression is halted. The patient can assume more responsibility for his or her outcome, and independence helps preserve self-esteem. These individuals remain closer to and more engaged with the people and situations with whom and with which they must learn to cope. Their morale may be rapidly improved by the combination of support, planning, and modest early treatment successes.

However, in some cases, these same factors may be disadvantageous. Routine tasks may seem overwhelming. High levels of conflict may render major relationships at least temporarily unworkable. Inpatient settings offer the advantage of respite, high levels of structure, more intensive professional and peer support, constant supervision, and, usually, more rapid pharmacologic and psychosocial intervention.

The choice of inpatient or outpatient setting will depend on the balance of strengths and weaknesses of the patient, the involvement and competence of family or friends, the availability of a therapist in the community, and the ongoing stresses in the patient's life. This decision is best made by a psychiatrist. Because a psychiatrist is not always present in many facilities, a trained mental health professional should optimally be on call to every ED. This may be a psychiatric social worker, nurse clinician, or psychologist. When such services are not available, it is appropriate to detain patients in the ED until a practitioner with specific competence is available or to transfer the patient to another facility for evaluation. Every U.S. state has laws that provide for the involuntary commitment of the mentally ill under circumstances that vary from state to state ([Chap. 141](#)). Any acute, deliberately self-injurious behavior would generally qualify. Chronic, repetitive dangerous behavior that is not deliberate, such as frequent unintentional opioid, alcohol, sedative-hypnotic, or illicit "recreational" psychoactive drug overdoses, warrants careful evaluation. In the absence of psychiatric illness, involuntary treatment is usually not necessary, but should be considered carefully if a patient appears unable to achieve self-care. The practitioner should be familiar with the criteria for commitment and the classes of health care professionals so empowered under state law.

There are other treatment interventions that can be provided in the emergency setting, including crisis intervention, substance abuse counseling, and family therapy. A single session in the ED may be sufficient to defuse a crisis or to spur the drug-abusing patient to seek help. Alternatively, the intervention may be initiated in the ED and continued as an outpatient.

Crisis intervention is a brief, highly focused therapy that seeks to deconstruct how a crisis occurred, with the intent of examining the patient's role. Often, patients have distorted perceptions of the crisis, and a gentle "correction" of catastrophic thinking can be extremely helpful. The crisis is presented to the patient as an unfortunate and perhaps tragic experience that the patient can overcome. Ideally, the patient should have a relief of symptoms and learn how crises may be avoided in the future. This insight intervention will likely fail for patients with severe depression because of the presence of profound hopelessness. It is most successful for patients who give a history of high functioning just prior to the crisis.

Interestingly, sustained contact with patients via letters, postcards, or telephone calls can reduce suicidal behavior in the months after their presentation. A toxicology service in Australia found that a "postcard intervention" significantly

reduced the rate of repeated self-poisoning by patients who presented to their ED for self-poisoning.²¹ The postcard was mailed to patients in a sealed envelope eight times over the 12 months after their initial presentation, and simply stated: “It has been a short time since you were here, and we hope things are going well for you. If you wish to drop us a note we would be happy to hear from you. Best wishes.” Although the proportion of patients who self-poisoned again did not differ in the experimental versus control group, the total number of self-poisoning episodes were halved for the experimental group on follow-up 24 months later.²¹ Follow-up data at 5 years indicated that this benefit was sustained, and that psychiatric admissions were reduced by one-third.²⁰ Other studies examining letter-writing or postcard interventions in various clinical settings have also shown some benefit when examining rates of attempted or completed suicide or psychiatric emergency department visits.^{63,71,84} Given that such interventions do not require many resources and are quite cost effective, they appear promising.

“Contracting for safety” was a popular technique in the past, and consists of patients being asked whether they can remain safe and agree not to engage in self-harm. However, there are no empirical data to show that it is effective, and in court cases it has not been protective in terms of liability for the clinician. It is not recognized as part of the standard of care for the suicidal patient, and if anything, it seems to provide the clinician with a false sense of security. Its use is not recommended except as a technique to engage in a larger discussion of a safety plan that delineates scenarios the patient might face after leaving the hospital, and possible coping strategies.⁵³

VIOLENCE

Aggression presents unique challenges to the emergency physician, the psychiatrist, the nurses, and the other staff. Moreover, aggression is intimately related to suicidal behavior. Chronic aggression and impulsivity are risk factors for suicidality. Like suicidal patients, aggressive patients are difficult to treat and they tend to elicit strong negative reactions in ED personnel.⁹⁶ In one study of violence in the ED, directors of emergency medicine residency programs were surveyed as to the frequency of verbal threats, physical attacks, and the presence of weaponry in the area. Of the 127 institutions surveyed, 74.7% of the residency directors responded; 41 (32%) reported receiving at least one verbal threat each day; moreover, 23 (18%) reported that weapons were displayed as a threat at least once each month. Fifty-five program directors (43%) noted that a physical attack on medical staff members occurred at least once a month.⁷⁷

Another study involved a retrospective review of university police log records and ED staff incident reports to examine the problem of violence in the ED setting. Almost 75% of the incidents occurred during the evening or night. Of the 686 episodes of violence in this study, more than 25% required physical restraint or removal from the premises. In addition, it was found that the hospital security responded to the ED nearly twice daily.⁸⁷ These studies underscore the need for timely identification of the violent patient, as well as appropriate management for this diagnostically heterogeneous group.³⁸ The assessment and management of the violent patient should include provisions for patient and staff safety as well as a thorough search for the cause of violent behavior.^{69,96}

This section addresses the differential diagnosis of violent behavior, the pharmacotherapy of aggressive and/or agitated behavior (often termed “chemical restraint”), and the use of seclusion and physical restraint. It also provides an overview of potential risk factors for violent behavior.

Stress-Vulnerability Model of Aggression

As in the case of suicide, there are many and varied causes of violent behavior, some more social and some more medical in nature. The stress-vulnerability model suggests that violence should be considered as the outcome of a dynamic interaction among numerous factors both intrinsic and extrinsic to the individual, some of which promote and some of which ameliorate the potential for violent behavior at any given moment. Education may provide alternatives to violence, but a xenobiotic-induced delirium will render any education ineffective since delirium prevents patients from reasoning or exercising impulse control. Once confused, the patient may misinterpret health care efforts in a paranoid manner, and become violent under circumstances that would not normally be sufficient to provoke a violent outburst. Some patients, on the other hand, come from cultures in which aggressive behavior is more acceptable, and these patients require little stress or provocation before responding in what can be perceived as aggression by Western cultural standards.

In the ED, likely medical sources of vulnerability include metabolic derangements, exposure to xenobiotic (both licit and illicit) withdrawal syndromes, seizure disorders, head trauma, psychosis, and personality disorders. Additionally, patients with severe pain, delirium, or extreme anxiety can respond to the efforts of emergency personnel with resistance, hostility, or frank aggression.

Prediction of Violence

Research on risk factors for community violence may not apply to the prediction of inpatient violence. Some researchers have postulated that violence committed outside the hospital may not be predictive of inpatient violence and that hospital

violence may result from the interaction of patients with specific factors found in the hospital environment.^{41,96} Other studies are contradictory.⁹⁸ Consequently, prior violence is not a perfect predictor of future violence. Other factors, such as mental illness and substance abuse, need to be examined to make meaningful predictions of inpatient violence for each individual case.⁹⁶ One study found that the most common types of hospital violence were incidents of aggression against objects in the hospital (57%), violence directed against the hospital staff (28%), and violence directed against other patients (14%).⁹⁷ In this study, men did not commit significantly greater incidents of violence than women. Other studies concur that men are not necessarily more of a risk for inpatient violence than women. For example, researchers examining inpatient violence found that close to half of the violent incidents were committed by women, and the number of violence-related injuries committed by men and women inpatients were almost proportional to the ratio of men and women inpatients on the unit.^{76,89} The conclusion was that gender should not be considered a risk factor for inpatient violence. Long hospitalization was not considered a factor predictive of violence for the majority of inpatients. As with outpatient violence, the correlation of violence with younger age appears to hold true in the inpatient setting.^{82,89,90}

Substance Use

The association between substance use and violence is well established. Alcohol is found in the offender, the victim, or both in one-half to two-thirds of homicides and serious assaults.^{30,89} Substance use is seldom the sole cause, but it may contribute to violence in a number of ways. The direct pharmacologic effects include disinhibition and misinterpretation, suspiciousness, or paranoia. Psychological effects of substance use include cultural expectations of appropriate behavior under the influence and the ability to excuse or disavow inappropriate behavior that occurs while intoxicated. Substance use then interacts with other physiologic, cognitive, psychological, situational, and cultural factors including any underlying mental illness. A tripartite model has been described: (1) systemic violence related to drug distribution, (2) economic compulsive violence associated with the criminal activity necessary to sustain a drug habit, and (3) psychopharmacologic violence resulting from the direct effects of the particular xenobiotic.^{55,56}

Mental Illness

The relationship between mental illness and violence is also complex. Efforts made to destigmatize mental illness have confused the issue, but it seems clear that mental illness is associated with an increased risk for violence.⁸⁹ In one large epidemiologic study, the prevalence of violence for those with no mental illness was 2%. Schizophrenia was associated with an 8% rate of violent behavior, and other mental disorders all had similar prevalence of approximately 12%. But of all respondents reporting violent behaviors, 42% had an SUD. Substance use more than tripled the rate of violence for individuals with schizophrenia. Mental illness appears to reduce the threshold for aggression, and the more comorbid conditions present, the greater the risk.^{85,104,105}

Researchers consistently find a greater prevalence of personality disorders among violent inpatients than among nonviolent inpatients.²⁴ However, antisocial personality is the condition most strongly associated with both substance use and aggression. In one study, when the history of juvenile deviant behavior was controlled for alcohol, the drug most commonly associated with violence, it accounted for only 2% of the violent behavior.

In conclusion, some aggressive behavior is attributable to the direct pharmacologic effects of xenobiotics, but probably represents only a modest fraction. Substance use is often implicated in violent behavior in the community, it can occur as a coincidental part of the lifestyle of violent individuals, and both substance use and violence are related to common underlying characteristics such as a personality disorder.

Additional Factors in Aggressive Behavior

Many of the factors correlated with aggression are easy to observe and monitor in the hospital, yet some additional factors may not be as easy to detect. For example, one study found that most violent incidents in the hospital occur on Mondays and Fridays, with very few incidents on weekends. Furthermore, researchers have postulated a seasonal variation of violence.³² There is an increase in the frequency of assaults by inpatients during the winter months, and it has been hypothesized that increased population density, cold temperature, and less sunlight during the day could account for the increased violence. This finding is in contrast to the literature on outpatient violence, which has reported greater incidence of violence during the warmer months.⁶ However, this same review conceded that any extreme temperature could evoke aggressive feelings and frustration. Yet another study examined the relationship between temperature and violence and found that more aggressive acts occur during the summer months, both in the hospital and in the community.⁵⁰ They cited several explanations, one of which was that the high rate of staff turnover (eg, vacations) disrupts the social networks that the patients have established, and evokes aggressive feelings.

Although it is unclear whether cold temperatures can provoke aggression as much as it has been established that heat can, it does seem clear that overcrowding and social stressors can lead to violent behavior. If the effects of temperature and social stressors (eg, holidays) correlate so drastically with violence in the community, it is likely that such effects would

have even more impact when comorbid with severe mental illness, substance use, or any of the other risk factors of aggression.

Assessment of the Violent Patient

The comprehensive evaluation of the violent patient should include a complete physical examination. The examination may reveal the underlying cause of the violent behavior as well as ensuring the treatment of any secondary patient injuries. Laboratory analysis may include blood chemistries (glucose, electrolytes, including sodium and calcium), a complete blood count, liver function tests, thyroid function tests, lumbar puncture and/or neuroimaging as guided by the examination and clinical history.

Substance Intoxication and Withdrawal. Illicit xenobiotic and alcohol use often present with symptoms of violence. Please refer to subsequent chapters for details on presentations of acute intoxication for specific substances.

Withdrawal syndromes can also promote aggressive behavior as a consequence of physical discomfort or anticipatory anxiety. Patients experiencing any of these symptoms may become aggressive, verbally abusive, or threatening. Prompt recognition of these syndromes and immediate treatment can prevent some aggressive outbursts. Because drug use is often concealed, is difficult to ascertain on clinical grounds, and frequently contributes to violent behavior, urine and blood toxicological studies may be useful to enhance the understanding and long-range treatment of some patients.⁸⁹

Alternative Etiologies. Delirium can be a cause of aggression. Patients are often suddenly confused, frightened, or frankly psychotic as a result of impaired perception. Patients may require sedation or physical restraint in order to prevent injury to themselves as well as staff members.

Although persons with psychotic disorders are not generally aggressive, there are aspects of their psychosis that place them at risk for aggressive behavior. Paranoid ideation can serve to promote misperceptions of impending bodily harm (“They’re trying to kill me”), sexual victimization (“Men and women are raping me”), or humiliation (“Everyone is laughing at me”). It follows that these fearful perceptions might provoke violent reactions in a patient. Hallucinations can lead to aggression, either when patients explicitly follow the instructions of a command auditory hallucination or in reaction to the anxiety and fear that patients can experience with loud or persistent auditory hallucinations (“hearing voices”). Patients with either borderline or antisocial personality disorder are at risk for violent acting out as a result of poor impulse control and impaired frustration tolerance in the context of poor coping skills.

Violence risk is also associated with cognitive dysfunction. Both acute mental illness and chronic substance use can result in neurologic impairment. Psychiatric patients with compromised cognitive abilities such as impaired attention, memory, or executive functioning, such as reasoning and planning, are found to be at increased risk for violence.⁸⁹ Patients presenting with cognitive impairment may also be at increased risk for committing acts of violence in the ED.

Treatment

The acute pharmacotherapy of violent behavior is directed simply at reducing the level of arousal. If agitation and violent outbursts are viewed as transient disturbances of the usual treatment relationship between the physician and patient, then pharmacotherapy, seclusion, and restraint are to be used as needed to restore that relationship for the benefit of the patient as well as staff.² Sleep delays rather than promotes assessment, may further frighten or anger the patient, and does not guarantee elimination of the agitated state on awakening. There are two main approaches to controlling aggressive behavior: chemical restraint and physical restraint.

Chemical Restraint. Chemical restraint is defined as “chemical measures for confining a patient’s bodily movements, thereby preventing injury to self or others and reducing agitation.”³⁷ Given that aggression can result from multiple etiologies, there is much debate about the specific sedative and route of administration that should be used. Overall, it has been found that both benzodiazepines and antipsychotics resulted in rapid control of agitation and aggression.^{19,45,74,76}

Haloperidol has been safely used in the treatment of agitation and aggression in patients with psychoses, acute alcohol intoxication, and delirium.^{1,19,74,76} It can be administered orally, intravenously, or intramuscularly. Dosing intervals range from 30 minutes to 2 hours, with a usual regimen of haloperidol 5 mg given every 30 to 60 minutes; most patients respond after one to three doses. Older studies indicated that the dose of haloperidol needed to achieve sedation rarely exceeded a total of 50 mg in acute management, but it is unusual that more than 20 mg is used today.^{78,79} Most psychiatrists would switch to a second-generation antipsychotic such as olanzapine or add a mood stabilizer such as valproic acid rather than continue to titrate haloperidol.

Benzodiazepines are also quite effective for sedation; their use has been examined in patients with psychoses, stimulant intoxication, sedative-hypnotic and alcohol withdrawal, and postoperative agitation.^{54,81} Diazepam may be given as intravenous (IV) 5 to 10 mg, with rapid repeat dosing titrated to desired effect. Because diazepam is poorly absorbed from intramuscular (IM) sites, its preferred route of administration is either IV or oral. Lorazepam 1 to 2 mg or midazolam 5 to 10 mg may be given orally or parenterally and repeated at 30- or 15-minutes intervals, respectively, until the patient is calm (Antidotes in Depth: A23). Midazolam is frequently used in the ED due to its quick onset of action and short half-life

of 1 to 4 hours, but it has a significant amnestic effect; lorazepam may be preferable since it is less amnestic and will provide longer anxiolysis given its slower elimination half-life of 10 to 20 hours.

If a patient is agitated in the context of alcohol intoxication, antipsychotics can be used but benzodiazepines should be avoided due to the potential to cause additive respiratory depression. Benzodiazepines may have a unique role in the treatment of agitation secondary to cocaine intoxication ([Chap. 78](#)). Antipsychotics, particularly low-potency antipsychotics (such as chlorpromazine), lower the seizure threshold in animals, so their use for patients with cocaine/amphetamine toxicity or alcohol/sedative-hypnotic withdrawal should be avoided. Some studies suggest that the combined use of lorazepam with antipsychotics in patients with known psychiatric illness and delirium afforded relief of psychotic symptoms while allowing for a reduced dose of antipsychotic medications.^{1,31,95} On psychiatric services, the combination of haloperidol and lorazepam is still the most frequently used IM pharmacotherapeutic intervention, likely due to the relative lack of data for second-generation antipsychotics combined with lorazepam.⁶¹

Special concern has been raised about oversedation and respiratory depression with IM olanzapine, given that eight fatalities were reported in the European literature when olanzapine was used in excessive dosages or combined with benzodiazepines and/or other antipsychotics; although significant comorbidities were present in the patients who died, it is now recommended that IM olanzapine should not be coadministered with other CNS depressants.¹¹ In general, concerns regarding respiratory depression mandate careful observation and monitoring of patients receiving sedation with any xenobiotic.

Physical Restraint. Isolation and mechanical restraints are also used in the treatment of violent behavior. Isolation or seclusion can help to diminish environmental stimuli and thereby reduce hyper-reactivity. However, a few aspects are worth mentioning: Because seclusion is defined by a condition of very limited interactive and environmental cues, it is not indicated for patients with unstable medical conditions, delirium, dementia, self-injurious behavior (cutting, head banging), or those who are experiencing extrapyramidal reactions as a consequence of antipsychotic medication (such as an acute dystonic reaction).³ Mechanical restraint is used to prevent patient and staff injury, although it does occasionally lead to patient and staff injury itself.^{9,61} All facilities should have clear, written policy guidelines for restraint that address monitoring, documentation, and provisions for patient comfort. Frequent reassessment of the patient and documentation of the need for continued restraint are essential, and should be performed according to state law. The Joint Commission standards require a renewed restraint order every 4 hours, but the physician (or licensed independent practitioner) is only required to evaluate the patient within the first hour and then every 24 hours. Other staff members provide ongoing monitoring at time intervals specified by the institution. The Joint Commission notes that state laws should be followed when they are more restrictive. Although there are limited controlled data at this point, numerous interventions are being considered in psychiatric settings as alternatives to de-escalate a patient before restraints are employed, and there is a general trend to attempt to reduce the use of mechanical restraints, although it seems doubtful that such restraints can be eliminated entirely.¹⁰⁰

Training. Finally, training in the management of aggression helps to reduce violence and injuries through the early identification of impending episodes of violence, use of verbal techniques to defuse incidents, and appropriate physical techniques to minimize injuries in those that occur. It is necessary for health care providers to maintain their skills through training and to advocate for continuing medical education on this topic at the workplace.^{17,93} See [Tables 27–6 and 27–7](#) for violence warning signs and the S.A.F.E.S.T. Approach.

TABLE 27–6. Violence Warning Signs

- Threatening statements
- Clenched fists
- Loud vocalizations
- Body posturing, rapid/shallow breathing
- Agitated movements
- Pacing
- Staring
- Striking at inanimate objects

TABLE 27–7. S.A.F.E.S.T. Approach⁴⁸

Spacing	Maintain a safe distance Allow both patient and you to have equal access to the door (but you should be closest) Do not touch the patient
Appearance	Maintain empathetic and professional detachment Use one primary person to build rapport Have security available as a show of strength
Focus	Watch the patient's hands Look for potential weapons Watch for escalating agitation
Exchange	Attempt to de-escalate by use of calm/continuous talking Avoid punitive or judgmental statements Use good listening skills Elicit patient cooperation by targeting the current problem
Stabilization	By the least restrictive means possible: Physical restraints Sedation (benzodiazepines) Antipsychotics
Treatment	Treat underlying cause May need to treat involuntarily

SUBSTANCE USE DISORDERS

SUDs are characterized by compulsive drug seeking and drug taking in a setting of loss of control, continued use despite negative consequences, and functional impairment in several areas of a person's life. They are highly comorbid with suicidality, violence, and mental illness as described above in previous sections. Prevalence rates of substance use in the ED range from 9% to 47%, depending on the sample.⁴⁶ ED physicians and medical toxicologists are in a unique position to identify substance use disorders and refer patients to additional treatment services. There is an extensive array of evidence-based treatment for SUDs, but fewer than 10% of persons with SUDs in the United States receive substance abuse treatment.

DSM-5 Diagnoses

The psychiatrist's diagnostic handbook, the Diagnostic and Statistical Manual of Mental Disorders (DSM), codifies various diagnoses involving the use of substances. The latest version is the 5th edition, DSM-5, which was released in 2013.⁴ While previous versions of the DSM differentiated "substance abuse" and "substance dependence," the DSM-5 combines these categories into an overarching "substance use disorder" diagnosis with mild, moderate, and severe specifiers. "Substance abuse" was considered to be a milder or earlier phase of an addictive disorder, while "substance dependence" was the more severe manifestation; however, in practice, substance abuse criteria were sometimes quite severe, and the distinction was not found to be clinically helpful. In the combined "substance use disorder" criteria found in DSM-5, the criterion of recurrent legal problems has been eliminated, and a new criterion for "craving" has been introduced. Table 27-8 shows the criteria for an alcohol use disorder, and the reader can use this as a template to substitute other substances of abuse as well.

TABLE 27-8. DSM-5: Criteria for Alcohol Use Disorder (2013)

Alcohol Use Disorder

Diagnostic Criteria

A. A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:

1. Alcohol is often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.

4. Craving, or a strong desire or urge to use alcohol.
5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.
8. Recurrent alcohol use in situations in which it is physically hazardous.
9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
10. Tolerance, as defined by either of the following:
 - a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect.
 - b. A markedly diminished effect with continued use of the same amount of alcohol.
11. Withdrawal, as manifested by either of the following:
 - a. The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for alcohol withdrawal).
 - b. Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

Specify if:

- **In early remission:** After full criteria for alcohol use disorder were previously met, none of the criteria for alcohol use disorder have been met for at least 3 months but for less than 12 months (with the exception that Criterion A4, “Craving, or a strong desire or urge to use alcohol,” may be met).
- **In sustained remission:** After full criteria for alcohol use disorder were previously met, none of the criteria for alcohol use disorder have been met at any time during a period of 12 months or longer (with the exception that Criterion A4, “Craving, or a strong desire or urge to use alcohol,” may be met).

Specify if:

- **In a controlled environment:** This additional specifier is used if the individual is in an environment where access to alcohol is restricted.

Code based on current severity: Note for ICD-10-CM codes: If an alcohol intoxication, alcohol withdrawal, or another alcohol-induced mental disorder is also present, do not use the codes below for alcohol use disorder. Instead, the comorbid alcohol use disorder is indicated in the 4th character of the alcohol-induced disorder code (see the coding note for alcohol intoxication, alcohol withdrawal, or a specific alcohol-induced mental disorder). For example, if there is comorbid alcohol intoxication and alcohol use disorder, only the alcohol intoxication code is given, with the 4th character indicating whether the comorbid alcohol use disorder is mild, moderate, or severe: F10.129 for mild alcohol use disorder with alcohol intoxication or F10.229 for a moderate or severe alcohol use disorder with alcohol intoxication.

Specify current severity:

- **305.00 (F10.10) Mild:** Presence of 2–3 symptoms.
- **303.90 (F10.20) Moderate:** Presence of 4–5 symptoms.
- **303.90 (F10.20) Severe:** Presence of 6 or more symptoms.

Neurobiology of Substance Use Disorders

It is helpful for the emergency physician to be able to recognize the signs and symptoms of an SUD. Although the DSM-5 criteria are straightforward, many patients may not be forthcoming and may not share the extent of their drug use and its

effect on their lives. In those cases, one can look for inconsistencies in either the history or the presentation. Denial is often prominent. For example, a patient might present intoxicated with an arm injury, but is unconcerned and dismissive about the incident when no longer intoxicated. One would expect a patient to demonstrate appropriate concern, rather than just “wanting to leave.”

One of the more vexing aspects of substance-dependent patients is the frequency with which they minimize the dangerousness of their actions or the severity of their presentation. This can be interpreted as a sign of prefrontal cortex dysfunction due to the addiction. The patient is incorrectly processing risks/benefits, and is increasingly driven to compulsive drug use at the cost of natural rewards such as food, sex, love, or safety. Initial drug use results in relaxation, euphoria, stress relief, or a variety of other psychological effects, as mediated by the dopaminergic “reward pathway.” It was traditionally taught that dopamine release in this pathway was synonymous with experiencing “pleasure,” but it has become apparent that the function of dopamine is more accurately portrayed as indicating “salience” (or importance). A burst of dopamine in this pathway confers enhanced salience onto a particular stimulus or aspect of the environment, which means that this stimulus now appears more important and there is greater motivation to pay attention to it. One can see how this works well as a survival system, with natural rewards such as food and sex resulting in increased dopamine and subsequently greater salience. Drugs of abuse essentially “hijack” this pathway by directly producing supraphysiologic dopamine increases that would normally not occur.⁷⁰

However, activity in the reward pathway only explains the acute effects of drugs, and does not mediate any enduring behavioral changes. The cravings and compulsive behavior that occur in addiction result from glutamate-mediated circuits that develop in the prefrontal cortex and establish aberrant connections to the limbic system. Areas affected include the orbitofrontal cortex, which regulates salience attribution, and the anterior cingulate gyrus, which regulates inhibitory control. Late-stage addiction is characterized by derangements in these areas of the prefrontal cortex, which lend increased salience to drugs of abuse coupled with reduced ability to inhibit behavior. Environmental “triggers” established by classical conditioning can subsequently act to induce powerful states of craving and motivation to find and use a particular drug.⁷⁰

Despite our sophistication in describing the neurobiology of addiction, it can be challenging for an individual clinician to act accordingly when dealing with an addicted patient; we are used to assuming that behavior is voluntary, especially if a person is coherent and oriented. It can be difficult to recall that a patient who is hostile and in denial actually has true neurobiologic dysfunction, not unlike a patient with dementia or psychosis. Unfortunately, our current civil commitment laws and society’s perception of these patients have not “caught up” with this neurobiological understanding.

Suicidality

Substance use itself (not necessarily as part of an SUD) is frequently comorbid with self-injurious behavior. Based on data from 16 reporting states in the National Violent Death Reporting System in 2009, 33.3% of suicide decedents tested positive for alcohol, 23% for antidepressants, 20.8% for opiates (including heroin and prescription analgesics).⁷³ As described earlier, patients often combine alcohol or illicit substances with prescription medication when multiple substances are used to self-poison.^{25,72} It is hypothesized that substance use can lead to disinhibition and the resultant ability to carry out an act of self-harm that may not have happened if the person had remained sober.

Treatment

Substance abuse treatment is ultimately an intermediate (weeks to months) to long-term (months to years) intervention. However, there are powerful initial steps that the emergency physician can take. Central among these is confronting the patient about the medical consequences of substance use. This can take the form of discussion only, or the physician can invite the patient to examine clinical laboratory results or view remarkable clinical diagnostic findings (hepatomegaly, repeated fractures from falls, liver enzyme abnormalities, or evidence of “silent” past myocardial infarction). There is little to be lost from a respectful but blunt confrontation of the patient’s deterioration, and the patient may listen to a physician rather than family or friends. “Physician advice” in this manner is shown to be useful for patients who do not yet meet criteria for substance dependence, and therefore still have sufficient control of their substance use to make a logical decision about the risks versus benefits of continued use.

Patients who are further along the addictive spectrum and who display behavioral or physiologic signs of substance dependence are much less likely to curb their substance use in the face of adverse medical sequelae. For these patients, more intensive intervention is warranted, often in the form of a consultation. For most hospitals, this type of consultation would be fulfilled by a psychiatrist, but some institutions have a separate substance abuse consult service. Ideally, all patients suspected to have an SUD should be referred to some type of aftercare when possible: inpatient or outpatient detoxification, inpatient or outpatient rehabilitation, or even follow-up with primary care.

In a busy ED this can be quite cumbersome logistically, depending upon the demographics of the patient population and the percentage of patients suspected to have an SUD. Regulatory agencies at the state and federal levels are increasingly mandating substance abuse screening, brief interventions, and referrals, so hopefully this will result in increased resources

for additional ancillary staff to assist with such tasks.

It is helpful to note that peer counseling is particularly useful in addictive disorders, and community 12-step programs like Narcotics Anonymous (NA) and Alcoholics Anonymous (AA) are ubiquitous worldwide. AA has its own website and specific phone lines in some cities that are staffed by AA members with the express purpose of orienting potential new members and assisting them in getting to their first meeting. Even if there is insufficient infrastructure in the ED to provide the more intensive intervention that might be needed for a patient who is substance-dependent, the physician can at least refer directly to AA. Patients with repeated presentations for substance intoxication/withdrawal should be considered for a higher level of care, since they may be demonstrating an inability to care for themselves. Such a decision would be made in conjunction with the psychiatrist and would have to comply with the local civil commitment laws. Finally, it is important to note that substance abuse treatment is quite effective, and that coerced treatment has been found to be just as effective as voluntary treatment. Given the remarkably high comorbidity of SUDs in the ED setting, it behooves us to attempt to connect these patients with the appropriate treatment.

SUMMARY

- Capacity assessment should be approached systematically, and such an approach is helpful in more complex situations. A “sliding scale” is a useful concept; when refusing an intervention would have serious consequences, a patient is held to a higher standard to demonstrate capacity.
- “Medical clearance” does not have a standard protocol, but in general the ED assessment should be guided by the history and physical examination.
- Both violent and suicidal behavior in the ED may be the cause or the effect of many toxicologic presentations.
- It is incumbent on all emergency physicians to screen patients for psychiatric emergency presentations as part of a comprehensive screening for self-harm.
- Identifying risk factors for suicide and aggression can aid the clinician in employing preventive or early intervention strategies in the ED.
- Important risk factors for both suicidal and violent behavior include past history of the behavior, comorbid mental illness, drug and alcohol intoxication, and young age.
- Mental status examination for suicidality should focus on extrinsic factors such as current ideation, intent, lethality of plan, current life stressors, as well as intrinsic vulnerability factors such as comorbid mental illness, feelings of hopelessness, and impulsivity.
- In terms of violence risk assessment, drug and alcohol intoxication, mental illness, and psychiatric medication noncompliance (alone or in combination) are robust predictors of aggressive behavior in the ED and other inpatient settings.
- Substance use disorders are highly prevalent in patients who present with psychiatric issues in the ED, and there are possibilities for identification and referral even in busy ED settings.

28 RENAL PRINCIPLES

Marc Ghannoum and David S. Goldfarb

ANATOMY AND BASIC PHYSIOLOGY

The kidneys lie in the paravertebral grooves at the level of the T12 to L3 vertebrae. The medial margin of each is concave, whereas the lateral margins are convex, giving the organ a bean-shaped appearance. In the adult, each kidney measures 10 to 12 cm in length, 5 to 7.5 cm in width, and 2.5 to 3.0 cm in thickness. In an adult man, each kidney weighs 125 to 170 g; in an adult woman, each kidney weighs 115 to 155 g.

On the medial surface of the kidney is the hilum, through which the renal artery, vein, renal pelvis, a nerve plexus, and lymphatics pass. On the convex surface, the kidney is surrounded by a fibrous capsule, which protects it, and a fatty capsule with a fibroareolar capsule called the renal fascia, which offers further protection and serves to anchor it in place.

The arterial supply begins with the renal arteries, which are direct branches of the aorta. On entering the hilum, the arteries subdivide into branches supplying the five major segments of each kidney: the apical pole, the anterosuperior segment, the anteroinferior segment, the posterior segment, and the inferior pole. These arteries subsequently divide within each segment to become lobar arteries. In turn, these vessels give rise to arcuate arteries that diverge into the sharply branching interlobular arteries, which directly supply the glomerular tufts.

The cut surface of the kidney reveals a pale outer rim and a dark inner region corresponding to the cortex and medulla, respectively. The cortex is 1 cm thick and surrounds the base of each medullary pyramid. The medulla consists of between 8 and 18 cone-shaped areas called medullary pyramids; the apex of each area forms a papilla containing the ends of the collecting ducts. Urine empties from each papilla into a calyx and the calyces join together to form the renal pelvis. Urine is drained from the pelvis into the ureters, and, subsequently, into the urinary bladder.

The kidneys serve three major functions: (1) homeostasis of fluids, acid-base balance, and electrolytes, (2) excretion of nitrogen, as urea, and other waste products, and (3) endocrine production (eg, 1,25-dihydroxy vitamin D, renin, erythropoietin).

The kidneys maintain the constancy of the extracellular fluid by creating an ultrafiltrate of the plasma that is virtually free of cells and larger macromolecules, and then processing that filtrate, reclaiming what the body needs and letting the rest escape as urine. Every 24 hours, an adult's glomeruli filter nearly 180 L of water (total body water is ~ 25–60 L) and 25,000 mEq of sodium (total body Na^+ content is 1200–2800 mEq). Under normal circumstances, the kidneys regulate salt and water excretion, depending on intake and extrarenal losses. Approximately 1% of the filtered water and 0.5% to 1% of the filtered Na^+ are excreted.

Renal function begins with filtration at the glomerulus, a highly permeable capillary network connecting two arterioles in series. The relative constriction or dilation of these vessels normally controls the glomerular filtration rate (GFR). Under healthy circumstances, the filtration fraction, the proportion of renal plasma that is filtered, is approximately 20%. Plasma water crosses the filter, along with electrolytes, small solutes such as glucose, amino acids, lactate, and urea; blood cells and most of the larger proteins, including albumin and globulins do not typically cross the filter, although recent observations suggest that more plasma proteins than previously thought are filtered and reclaimed by the proximal tubule. The filtrate then enters the tubules, the serial segments of which have varying roles to metabolize, reabsorb, and secrete various solutes.

The proximal tubule performs the bulk of reabsorption, isotonicly reclaiming 65% to 70% of the filtrate. Distal to the proximal tubule is the loop of Henle, which controls concentration and dilution of the urine and plays an important role in the balance of Na^+ , Ca^{2+} and Mg^{2+} . The distal convoluted tubules also reabsorb Na^+ and Ca^{2+} and are joined by the connecting tubules to form the collecting ducts, which do the fine-tuning in the balance between excretion and reclamation of water, urea, K^+ , and H^+ . Paracellular reabsorption of sodium is controlled proximally by hydrostatic and oncotic pressures between the peritubular capillaries and the tubule while transcellular reabsorption is stimulated by angiotensin II. In the distal tubule, hormones such as aldosterone, and a variety of kinases control sodium transport. Control of water balance, dilution, and concentration depends first on function of the ascending limb of the loop of Henle, which absorbs solute without water. This produces a dilute tubular fluid and at the same time makes the medullary interstitium hypertonic. Final regulation of water reabsorption is related to the concentration of antidiuretic hormone (ADH; or vasopressin), which moves water-reabsorbing channels (aquaporins) into the membranes of the collecting ducts. The kidneys also regulate the

balance of potassium and hydrogen ions (which are influenced by the effect of aldosterone on the distal nephron), and calcium and phosphate via circulating parathyroid hormone, activated vitamin D, and fibroblast growth factor 23.

XENOBIOTICS AND THE KIDNEYS

Xenobiotics may affect kidney function in various ways and, conversely, renal disease may influence drug pharmacokinetics and lead to dangerous underdosing or overdosing. In the latter case, renal failure, whether acute or chronic, reduces the clearance of drugs eliminated by the kidneys. This may lead to drug accumulation and potential toxicity. The ideal dosing of drugs such as gabapentin, digoxin, baclofen, and vancomycin can vary several fold in patients with kidney failure compared to those with intact renal function. Some non-therapeutic xenobiotics may be potentially toxic in patients with kidney impairment while being relatively benign in patients with normal GFR. This is the case for gadolinium-based contrast used for magnetic resonance imaging, which carries the risk of nephrogenic systemic fibrosis.⁴⁶

Drug dosing in patients dependent on hemodialysis or peritoneal dialysis further complicates pharmacokinetics; in particular, the behavior of many antimicrobials can be severely altered in critically ill patients with kidney failure, whether acute or chronic. In this setting, the risk of underdosing with subsequent therapeutic failure and breakthrough resistance acquired by microorganisms may surpass that of drug accumulation. A notable example is fluconazole: the required dosage in patients undergoing continuous renal replacement therapy may surpass drug requirement in patients with intact renal function.⁵¹ For those drugs of which a substantial fraction is removed by hemodialysis, drug dosing after dialysis is often recommended. The use of therapeutic guides is encouraged to ensure proper drug prescription in patients with a history of kidney disease.³

Many xenobiotics cause or aggravate renal dysfunction. The kidneys are particularly susceptible to toxic injury for four reasons²⁶: (1) they receive 20% to 25% of cardiac output, yet make up less than 1% of total body mass implying a relatively large exposure to circulating xenobiotics, (2) they are metabolically active, and thus vulnerable to xenobiotics that disrupt metabolism or are activated by metabolism, such as acetaminophen (APAP), (3) they remove water from the filtrate which increases tubular concentration of xenobiotics, and (4) the glomeruli and interstitium are susceptible to attack by the immune system. Many factors, such as renal perfusion, can affect an individual's reaction to a particular nephrotoxin.⁴ Clinicians should be aware of these factors and, when possible, alter them to minimize the adverse effect after a toxic exposure.

Xenobiotics can affect any part of the nephron (Fig. 28–1), although not every type of toxic renal exposure will result in loss of GFR. The following will be described: (1) acute kidney injury, (2) chronic kidney disease, and (3) functional kidney disorders.

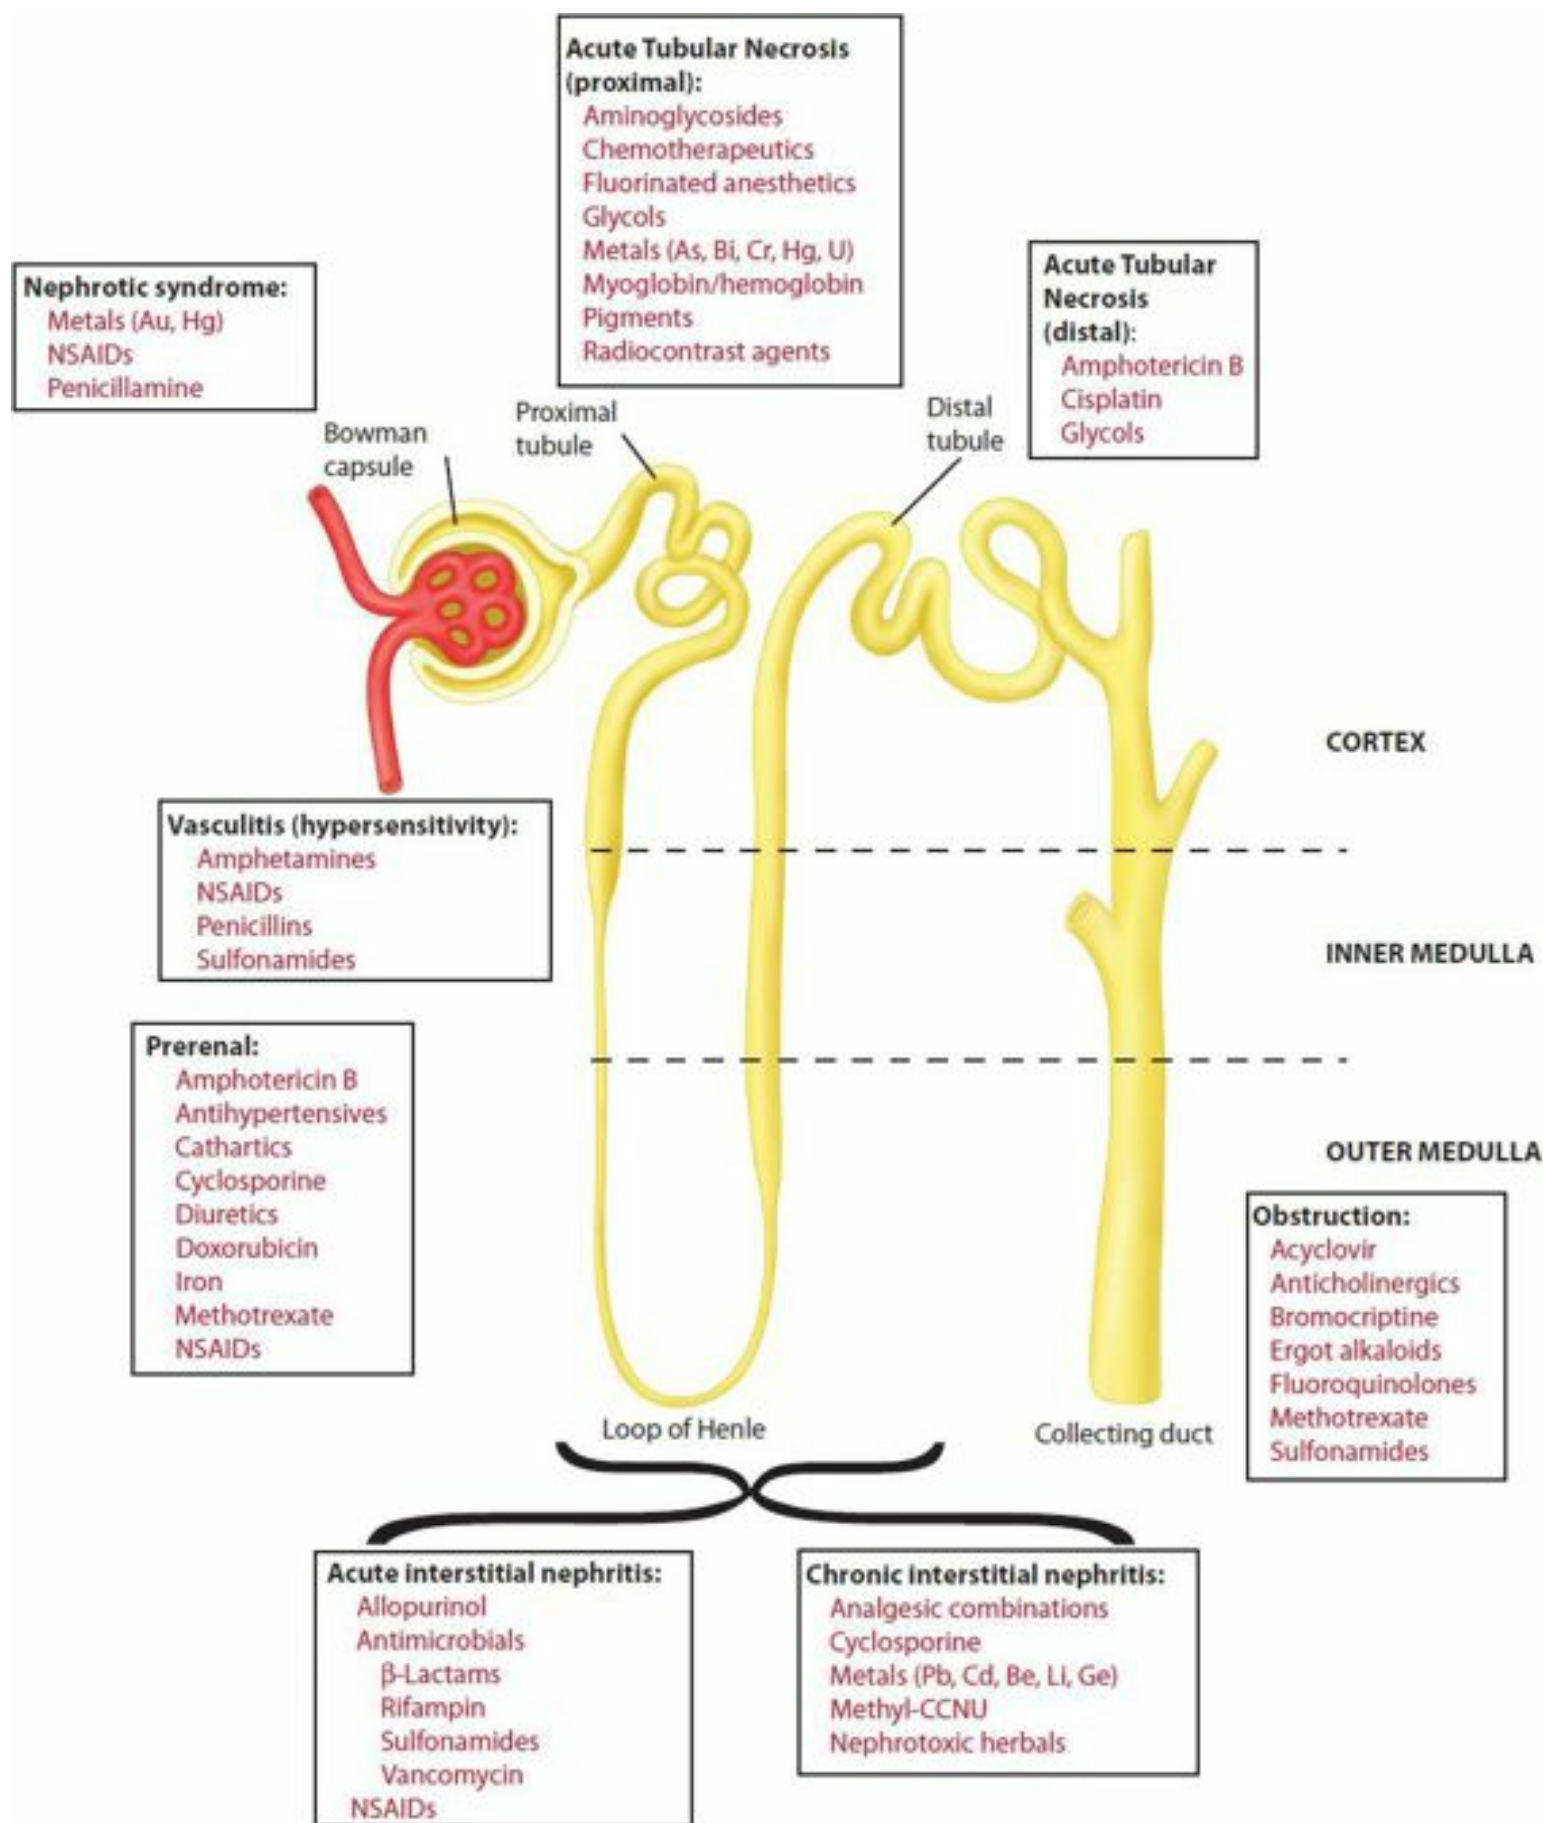

FIGURE 28–1. Schematic showing the major nephrotoxic processes and the sites on the nephron that they chiefly affect.

Acute Kidney Injury

Acute kidney injury (AKI; formerly called “acute renal failure”) relates to an abrupt decline in renal function that impairs the capacity of the kidney to maintain metabolic balance.

Several recent definitions of AKI have now been proposed, although they will likely be revised with the advent of newer and more specific biomarkers of kidney injury. The Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines introduced staging criteria for AKI, based on prior work from Acute Dialysis Quality Initiative (ADQI) and Acute Kidney Injury Network (AKIN) (Table 28–1).

TABLE 28–1. Kidney Disease Improving Global Outcomes (KDGO) Staging Criteria of Acute Kidney Injury

Stage 1	Creatinine of 1.5–1.9 times baseline
	OR
	≥ 0.3 mg/dL (≥ 26.5 μmol/L) increase in the serum creatinine
Stage 2	OR
	urine output < 0.5 mL/kg/h for 6–12 hours
	Creatinine of 2.0–2.9 times baseline increase in the serum creatinine
Stage 3	OR
	urine output < 0.5 mL/kg/h for ≥ 12 hours
	Creatinine of 3.0 times baseline increase in the serum creatinine
	OR
	increase in serum creatinine to ≥ 4.0 mg/dL (≥ 353.6 μmol/L)
	OR
	urine output of < 0.3 mL/kg/h for ≥ 24 hours
	OR
	anuria for ≥ 12 hours
	OR
	initiation of renal replacement therapy
	OR
in patients < 18 years, decrease in estimated GFR to < 35 mL/min per 1.73 m ²	

The three main categories of acute kidney injury are prerenal, postrenal, and intrinsic AKI.

Prerenal AKI. Prerenal AKI implies impaired renal perfusion, which can occur with volume depletion, systemic vasodilation, heart failure, or preglomerular vasoconstriction. Renal hypoperfusion initiates a sequence of events leading to renal salt and water reabsorption.⁴ Renin is released, causing production of angiotensin II, which enhances proximal tubular sodium reabsorption and stimulates adrenal aldosterone release, thus increasing distal sodium reabsorption. Therefore, prerenal AKI is usually accompanied by low urinary sodium excretion. Release of ADH increases water and urea retention. Histologically, the kidney appears normal. However, recent data showing elevated urinary content of molecules thought to represent kidney injury suggest a less benign course.

Any toxic exposure that compromises renal perfusion may contribute to prerenal AKI including bleeding (eg, overdose of anticoagulants), volume depletion (diuretics, cathartics, or emetics), cardiac dysfunction (β-adrenergic antagonists), or hypotension from any cause can lead to acute prerenal AKI.⁹ Nonsteroidal antiinflammatory drugs (NSAIDs) lower filtration rate by inhibiting production of vasodilatory prostaglandins in the afferent arteriole. Finally, cardiotoxins, such as doxorubicin, can cause severe heart failure (Fig. 28–1). Calcineurin inhibitors (cyclosporine, tacrolimus) may cause prerenal vasoconstriction by their effect on both afferent and efferent arterioles, possibly induced by endothelin. Calcineurin nephrotoxicity is usually dose-dependent and especially occurs when trough concentrations remain supratherapeutic for an extended period of time. Nephrotoxicity is often reversible after temporary discontinuation or decrease in the calcineurin dose if identified relatively quickly.

Prerenal AKI can also be caused by the hepatorenal syndrome, which is characterized by progressive renal hypoperfusion in the context of severe acute or chronic liver failure, marked constriction of the renal arterial vasculature and systemic hypotension. Circulating mediators of vasoconstriction that are subsequently increased include angiotensin, norepinephrine, vasopressin, endothelin, and isoprostane F₂ all contribute to an extreme cortical vasoconstriction. That the cause of AKI is extrarenal is best illustrated by the fact that when a kidney from a patient with hepatorenal syndrome is transplanted into a uremic patient, the function of the graft promptly returns to normal.

Finally, the entity known as the abdominal compartment syndrome is becoming increasingly recognized as a potential cause of renal hypoperfusion. Abdominal compartment syndrome is usually defined as new organ dysfunction induced by intraabdominal hypertension. Abdominal compartment syndrome may be observed when the intraabdominal pressure exceeds 20 mm Hg, especially if sustained. This abdominal hypertension may then induce renal artery vasoconstriction and impede venous drainage. Abdominal compartment syndrome can be caused by several entities, but usually requires some abdominal event, especially with concomitant aggressive fluid resuscitation. Surgical decompression is life-saving in this context.

Renal AKI. Renal AKI implies intrinsic damage to the renal parenchyma, which can be divided into vascular, glomerular, and tubulointerstitial etiologies.

Vascular etiologies of AKI includes vasculitis, malignant hypertension, atheroemboli, scleroderma, and hemolytic-

uremic syndrome or thrombotic thrombocytopenic purpura (HUS/TTP), the latter of which can sometimes be associated with use of certain xenobiotics (Table 28–2).

Gemcitabine

Mitomycin C

Quinine

Clopidogrel

Ticlopidine

Glomerular diseases infrequently cause acute AKI, but more commonly either chronic or subacute decline in kidney function. Glomerular lesions can present with the nephrotic or nephritic syndrome. A nephritic pattern is associated with histological inflammation, an active urine sediment with proteinuria and hematuria, and impaired kidney function. Hypertension is common. Nephrotic syndrome is characterized by massive proteinuria (>3.5 g/day), hypoalbuminemia, hyperlipidemia, and pitting pedal edema that usually prompts the patient to seek medical attention. Although the relationships among these findings are not completely understood, the underlying event is injury to the glomerular barrier that normally prevents macromolecules from passing from the capillary lumen into the urinary space. Xenobiotics induce nephrotic syndrome (Table 28–3) in two ways. First, they may release hidden antigens into the blood, which leads to antigen–antibody complex formation after the immune response is elicited. These complexes subsequently deposit in the glomerular basement membrane, thereby changing its properties (eg, gold)¹⁶ (Fig. 28–2). Second, they can upset the immunoregulatory balance.

FIGURE 28–2. Membranous glomerulonephropathy (secondary to gold), a cause of nephrotic syndrome. Globally thickened glomerular capillaries (red arrow) and interstitial foam cells (black arrow) are seen. Hematoxylin and eosin stain $\times 450$. (Used with permission of Dr. Rabia Mir.)

Penicillamine

Probenecid

Sirolimus

Kidney biopsy will permit identification of the characteristic pathologic pattern, either minimal glomerular change disease, membranous glomerulopathy, or focal segmental glomerulosclerosis. Hypoalbuminemia usually is worse than urinary excretion of albumin would suggest, as a result of renal tubular catabolism of filtered protein. The tubules also retain sodium, causing expansion of the extracellular space and edema. The glomerular lesion may progress to end-stage renal disease (ESRD) if the pathologic process continues.

The major causes of acute tubulointerstitial diseases include acute tubular necrosis (ATN), acute interstitial nephritis (AIN), and tumor lysis syndrome. Although there is controversy about how a tubular lesion leads to glomerular shutdown, it is generally felt that tubular obstruction, back-leak of filtrate across injured epithelium, renal hypoperfusion, and decreased glomerular filtering surface combine to impair glomerular filtration.⁴⁴ Additionally, filtration pressure is diminished by neutrophil infiltration into the interstitium and vasa recta.⁴⁸ Evidence also suggests that prolonged medullary ischemia, perhaps caused by an imbalance in the production of vasoconstrictors such as endothelin and vasodilators such as nitric oxide, is important in prolonging the renal dysfunction after the tubular injury develops.²³

ATN is the most common cause of AKI in hospitalized patients (Table 28–4).²⁷ ATN is manifested pathologically by patchy necrosis of the tubular epithelium and occlusion of the lumen by casts and cellular debris (Fig. 28–3). Clinically, ATN presents as a rapid deterioration of renal function. Muddy brown casts or renal tubular cells may be seen in the urinary sediment, but hematuria and leukocyturia are unusual. Disorders of metabolic balance, such as hyperkalemia and metabolic acidosis, are also common. The abrupt fall in GFR usually leads to positive sodium and water balance.³⁰

Paraquat, diquat

Radiocontrast agents (iodinated contrast, gadolinium)

ATN occurs following an ischemic or toxic injury.³⁵ Direct toxicity accounts for approximately 35% of all cases of ATN.⁴⁵ Xenobiotics can affect different segments of the renal tubules; for example, uranium attacks the proximal tubule and amphotericin the distal tubule⁴⁰ (Fig. 28–1). Certain xenobiotics cause a sudden or progressive decrease in GFR with concomitant prominent tubular wasting for electrolytes, though mechanisms of injury vary; this is the case of ifosfamide,¹⁷ amphotericin B,⁴⁰ aminoglycosides,³⁹ pentamidine,²⁹ and cisplatin.² Poisoning may also lead to ischemic tubular necrosis if hypotension or cardiac failure causes prolonged ischemia of nephron segments (proximal straight tubule and inner medullary collecting duct) that are particularly vulnerable to hypoxia. Patients who receive significant amounts of colloids (specifically mannitol, dextran, or hydroxyethyl starch)¹⁴ can occasionally develop AKI, characterized by tubular vacuolization or “osmotic nephrosis.” Iodinated contrast can cause AKI by mediating medullary vasoconstriction and inducing reactive oxygen species in tubules. Whatever the clinical pattern of rapidly declining renal function, all forms of ATN usually present with oliguria. Aminoglycosides are one exception: kidney failure, which may appear after several days of exposure, is nonoliguric.²⁵

Pigmenturia (myoglobinuria following rhabdomyolysis or hemoglobinuria from massive hemolysis) may also cause tubular injury and necrosis by precipitating in the tubular lumen.^{11,35} Myoglobin is normally excreted without causing toxicity. A study of patients with rhabdomyolysis suggests that the concentration of myoglobin in the urine may affect the development of AKI.¹¹ If myoglobin inspissates in the tubular lumen because of renal hypoperfusion and high urinary concentration, it dissociates in the relatively acidic environment as H⁺ is secreted, releasing tubulotoxic hematin. This toxicity may stem from the iron-catalyzing production of oxygen free radicals.

Rhabdomyolysis is most often caused by direct muscle injury following trauma or prolonged immobilization (Table 28–5). Any poisoning causing extended unconsciousness (eg, opioids and sedative-hypnotics), hyperthermia (neuroleptic malignant syndrome), excessive muscle contraction (cocaine, amphetamines),^{24,33} or tonic-clonic seizures (alcohol withdrawal, theophylline, isoniazid) may therefore lead to muscle breakdown.¹³ Other xenobiotics are directly myotoxic in some individuals, such as alcohol,²⁰ HMG-CoA reductase inhibitors (statins),¹⁸ carbon monoxide, copper sulfate, and zinc phosphate.^{28,50} Rhabdomyolysis can also occur after extensive bee or wasp stings¹⁹ or fire ant bites.²² Hypokalemia and hypophosphatemia (which may follow diuretics and laxatives abuse) can also induce rhabdomyolysis.

TABLE 28–5. Xenobiotics Causing Rhabdomyolysis

Alcohol

Antipsychotics

Carbon monoxide

Colchicine

Doxylamine

Drugs of abuse (heroin, cocaine, amphetamines, D-lysergic acid diethylamide, phencyclidine)

Drugs causing hypokalemia or hypophosphatemia

Selective serotonin reuptake inhibitors

Drugs causing prolonged central nervous system depression (immobilization) or seizures

Snake and insect venoms

Statins (especially when prescribed with fibrates)

Zidovudine

Hemoglobinuria follows hemolysis, which can be caused by a number of xenobiotics, including snake and spider venoms, cresol, dapsone, phenol, aniline, arsine, stibine, naphthalene, dichromate, and methylene chloride. Sensitivity reactions to drugs (hydralazine, quinine) can also cause hemolysis.²¹ The pathophysiology of hemoglobinuric ATN resembles that of myoglobinuria. The pigment deposits in the tubules and dissociates, causing necrosis to occur.³⁵ Volume depletion and acidosis precipitate the disorder; therefore, volume expansion and alkalinization may help prevent kidney injury.

Differentiation of ATN and prerenal AKI may be difficult clinically especially in critically ill patients; [Table 28–6](#) illustrates empiric criteria to separate them, although there are numerous exceptions to these. These exceptions should always be considered and correlated with clinical status. For example, fractional sodium excretion (the proportion of filtered sodium that appears in the urine, FE_{Na}) can be paradoxically high in prerenal AKI associated with metabolic alkalosis, diuretics, or adrenal insufficiency ([Table 28–7](#)). FE_{Na} can also be low in renal AKI secondary to rhabdomyolysis or contrast-induced AKI. Furthermore, distinction between both entities is difficult when there is exposure to xenobiotics capable of affecting the kidneys in various ways. NSAIDs, for example, can cause prerenal AKI, ATN, acute interstitial nephritis, analgesic nephropathy, or membranous nephropathy.

TABLE 28–6. Differentiation between Prerenal Acute Kidney Injury and Acute Tubular Necrosis

	<i>Prerenal Acute Kidney Injury</i>	<i>Acute Tubular Necrosis</i>
Fractional excretion of sodium (FE_{Na})	< 1%	> 2%
Fractional excretion of urea (FE_{Urea})	< 35%	> 50%
Serum urea/creatinine	> 20	10–15
Urine osmolality	> 400 mOsm/kg H ₂ O	Equivalent to plasma (isosthenuric)
Urine sodium	< 20 mEq/L	> 40 mEq/L
Urine sediment	Bland	Muddy “dirty” brown casts

TABLE 28–7. Calculations

Fractional Na ⁺ excretion (FE _{Na}) =	$\frac{([Na]_{urine}/[Na]_{plasma}) \times 100}{([Creat]_{urine}/[Creat]_{plasma})}$
Fractional Urea excretion (FE _{Urea}) =	$\frac{([Urea]_{urine}/[Urea]_{plasma}) \times 100}{([Creat]_{urine}/[Creat]_{plasma})}$
Creatinine clearance (by urine collection) =	$\frac{([Creat]_{urine} \times \text{urine flow})}{([Creat]_{plasma})}$
Estimated creatinine clearance (by Cockcroft-Gault formula) =	$\frac{(140 - \text{age}) \times \text{ideal body weight}}{(72 \times [Creat]_{plasma})(\times 0.85 \text{ if female})}$
Estimated glomerular filtration rate = (MDRD formula)	$\frac{186 \times [Creat]_{plasma}^{-1.154} \times \text{Age}^{-0.203}}{(\times 0.74 \text{ if female}) \times (1.21 \text{ if African American})}$

Units: urine flow (mL/min), creatinine concentration (mg/dL), weight (kg), age (years). N.B. these formulae are only applicable in a steady state (ie, if renal function is stable). MDMR = Modification of Diet in Renal Disease.

The other major tubulointerstitial cause of AKI is AIN (Table 28–8), which is characteristically distinguished from ATN by a dense cellular infiltrate separating tubular structures on renal biopsy (Fig. 28–4). Nearly all cases of acute interstitial nephritis are caused by hypersensitivity.⁴⁷ The diagnosis may be clear and kidney biopsy not necessary if kidney failure follows exposure to culpable drugs and is accompanied by classic manifestations of systemic allergy such as fever, rash, or eosinophilia, although only 10% of patients typically present with this classic triad.⁵ Flank pain or arthralgia may also be present. Unlike those with ATN, most patients with AIN have hematuria and leukocyturia,¹ particularly eosinophiluria, which is specific to this disorder.³⁴ The development of AIN is not dose-dependent and usually improves after cessation of the offending xenobiotic, although corticosteroids may hasten recovery in severe cases.

FIGURE 28–4. Acute interstitial nephritis (secondary to rifampin). Interstitial edema and patchy lymphocyte, plasma cell, and eosinophil infiltration occur without fibrosis (↗). Tubular epithelium shows degenerative and regenerative changes (↘) and mononuclear cell infiltration (tubulitis) (↖). (A) Hematoxylin and eosin stain × 112; (B) Hematoxylin and eosin stain × 450. (Used with permission of Dr. Rabia Mir.)

TABLE 28–8. Xenobiotics Causing Acute Interstitial Nephritis

Allopurinol

Anticonvulsants (carbamazepine, phenobarbital, phenytoin)

Antimicrobials (β -lactams, especially methicillin and cloxacillin, ciprofloxacin, sulfonamides, vancomycin, rifampin, nitrofurantoin, aminoglycosides, tetracyclines, colistin)

Azathioprine

Chinese herbs (*Stephania tetrandra*, *Magnolia officinalis*)

Diuretics (furosemide, thiazides)

H₁-antagonists (cimetidine, ranitidine)

Nonsteroidal antiinflammatory drugs (including selective cyclooxygenase-2 inhibitors)

Proton-pump inhibitors

Sulfinpyrazone

Zoledronate

Tumor lysis syndrome also affects the tubulointerstitium and usually occurs following chemotherapy for large bulk tumors. The incidence of tumor lysis has decreased with better procedural hydration and premedication with allopurinol or rasburicase.

Postrenal AKI. Postrenal AKI implies obstruction of urine flow anywhere from the renal pelvis to the urethra. Regardless of the cause of urinary tract obstruction, there are characteristic histologic and pathophysiologic alterations in the kidney: tubular dilation, predominantly in the distal tubule and collecting ducts, occurs initially and glomerular structure is preserved; subsequently dilation of the Bowman space occurs, and finally periglomerular fibrosis develops. Tubular function is impaired such that concentrating ability, potassium secretory function, and urinary acidification mechanisms are all altered.

Urinary tract obstruction should always be considered when the kidneys fail rapidly. Other risk factors include having a solitary kidney or a history of abdominal or genitourinary malignancy. Sudden anuria is a classical but rare feature of obstructive nephropathy; alternating phases of oliguria and polyuria are more common. Continued production of urine in the presence of obstruction leads to distension of the urinary tract above the blockage. Calyceal dilation is common. Obstruction of the bladder outlet or urethra may distend the bladder.

Obstruction may be caused by xenobiotics (Table 28–9). Most do so by impairing contraction of the bladder through anticholinergic action (atropine, antidepressants). Rarely, certain xenobiotics, particularly methysergide,⁴³ cause retroperitoneal fibrosis and ureteral constriction. Finally, a few xenobiotics lead to crystalluria and intratubular obstruction (eg, oxalosis in ethylene glycol poisoning³⁷). Sometimes the xenobiotic itself forms precipitates (sulfonamides, atazanavir, or methotrexate).^{7,42,49}

TABLE 28–9. Xenobiotics Causing Postrenal Acute Kidney Injury

<i>Bladder Dysfunction</i>	<i>Crystals</i>	<i>Retroperitoneal Fibrosis</i>
Anticholinergics (antihistamines, atropine, cyclic antidepressants, scopolamine)	Acyclovir	β -Adrenergic antagonists
Antipsychotics (butyrophenones, phenothiazines)	Ciprofloxacin	Bromocriptine
Bromocriptine	Diethylene glycol	Herbals (<i>Stephania</i> spp, <i>Aristolochia</i> spp)
Central nervous system depressants	Ethylene glycol	Hydralazine
	Fluorinated anesthetics	Methyldopa
	Fluoroquinolones	Methysergide
	Heme pigments	Pergolide
	Indinavir, nelfinavir, saquinavir, atazanavir	
	Melamine	
	Methotrexate	
	Phenylbutazone	
	Sulfonamides	
	Vitamin C	

Patients who present with acutely deteriorating kidney function often represent a difficult diagnostic challenge. Not only are there three major etiologic categories, each category has several subdivisions; and more than one factor may be present. For example, a patient with an opioid overdose may have neurogenic hypotension (prerenal), together with muscle necrosis causing myoglobinuric renal failure (intrinsic renal), and opioid-induced urinary retention (postrenal). Because renal, prerenal, and postrenal processes are not mutually exclusive and require different interventions, all three should always be considered, even when one appears to be the most obvious cause of the kidney failure.

Chronic Kidney Disease

Chronic kidney disease (CKD) refers to a disease process of a minimum duration of 3 months that often causes progressive decline of renal function. There is usually a gradual rise in blood urea nitrogen (BUN) and serum creatinine concentration as the GFR falls; unless advanced, there are often no clinical manifestations other than hypertension and nocturia (indicating loss of urinary concentrating ability). Classification of various stages of CKD, presently endorsed by KDIGO, is presented in [Table 28–10](#).

TABLE 28–10. Classification of Chronic Kidney Disease as Defined by the Kidney Disease Outcomes Quality Initiative and Modified and Endorsed by the Kidney Disease Improving Global Outcomes⁸

Stage	GFR	Description
1	≥ 90	Any kidney damage with normal or ↑ in GFR
2	60–89	Kidney damage with mild ↓ in GFR
3a	45–59	Mild to moderate ↓ in GFR
3b	30–44	Moderate to severe ↓ in GFR
4	15–29	Severe ↓ in GFR
5	< 15 or on dialysis	Kidney failure

GFR = glomerular filtration rate.

Reproduced with permission from Eckardt KU, Berns JS, Rocco MV, Kasiske BL. Definition and classification of CKD: the debate should be about patient prognosis—a position statement from KDOQI and KDIGO. *Am J Kidney Dis*. 2009;June;53(6):915–920.

In industrialized countries, most of the cases of CKD are caused by diabetes, hypertension, or glomerulonephritis. Nevertheless, many xenobiotics are implicated as nephrotoxins in long-term exposures. The most common lesion of nephrotoxic CKD is chronic interstitial nephritis ([Fig. 28–5](#)), which involves destruction of tubules over a prolonged period,¹² with tubular atrophy, fibrosis, and a variable cellular infiltrate ([Fig. 28–5](#)), sometimes accompanied by papillary necrosis. This then leads to ureteral colic via papillary sloughing. Acute interstitial nephritis may progress to chronic interstitial nephritis, if exposure is prolonged.⁴¹ Analgesic nephropathy was a common etiology of CKD until certain analgesics (such as phenacetin) were discontinued.³⁶ Chronic interstitial nephritis presents with mild to moderate proteinuria that remains well under the nephrotic range. Unlike other chronic renal disorders, it is characterized by failure of the diseased tubules to adapt to the renal impairment, resulting in metabolic imbalances such as hyperchloremic metabolic acidosis, sodium wasting, and hyperkalemia early in the disease course.¹⁰ Injury to erythropoietin-secreting cells may produce a disproportionate anemia.

FIGURE 28–5. Chronic interstitial nephritis (secondary to NSAIDs). Interstitial fibrosis (→), lymphocytic infiltration (→), and tubular atrophy (↙). Hematoxylin and eosin stain $\times 225$. (Used with permission of Dr. Rabia Mir.)

Functional Toxic Renal Disorders

Although most toxic renal injury results in decreased renal function, certain functional disorders can also upset systemic balance despite normal GFR in anatomically normal kidneys. Three examples are presented here: renal tubular acidosis (RTA), syndrome of inappropriate secretion of ADH (SIADH), and diabetes insipidus.

RTA is a loss of ability to reclaim the filtered bicarbonate (proximal type 2 RTA) or a decreased ability to secrete protons and generate new bicarbonate to replace that lost in buffering the daily acid load (distal type I RTA). In either case, there is a nonanion gap hyperchloremic metabolic acidosis (Chap. 19).

The primary defect in distal RTA (also called type 1 RTA) involves the decreased secretion of protons (H^+) from the intercalated cells of the distal tubule. This defect is most frequently the result of a defect in the H^+ -translocating adenosine triphosphatase (ATPase) on the luminal surface of these cells. Less frequently occurring mechanisms include abnormalities of the chloride-bicarbonate exchanger, which is responsible for returning bicarbonate generated within the cell to the systemic circulation. Also, given the voltage dependence of proton secretion, a decrease in the luminal electronegative charge will cause a decrease in its secretion. Most of this voltage is created by the activity of the Na^+-K^+ -ATPase on the peritubular capillary side of the adjacent cell. (Note: Cells adjacent to the intercalated cells are called principal cells and primarily control water absorption and K^+ secretion.) As this pump malfunctions, less sodium is returned to the capillaries, creating a decreased gradient from the lumen to the cell. Thus, the lumen becomes more electropositive, diminishing the transmembrane potential. Amphotericin B and some analgesics can cause distal RTA by allowing secreted H^+ to leak back into the tubular cells.⁶

The primary defect in proximal type 2 RTA is incompletely understood. Normally, the Na^+-H^+ exchanger in the luminal membrane, the Na^+-K^+ -ATPase in the basolateral membrane, and the enzyme carbonic anhydrase are the key systems necessary for proximal tubular bicarbonate reabsorption. If one or more of these mechanisms becomes disordered, then the resorptive capacity of the proximal tubule is diminished. Proximal RTA often occurs as part of the Fanconi syndrome, a generalized failure of proximal tubular transport (proximal RTA plus aminoaciduria, glycosuria, and hyperphosphaturia). Xenobiotics associated with type 2 RTA include aminoglycosides, lead, ifosfamide, mercury, and acetazolamide.

What was once known as type 3 RTA is recognized to be a combination of features of both distal and proximal RTA and affects infants as part of an autosomal recessive syndrome. Type 4 RTA is caused by a deficiency of aldosterone or by tubular resistance to its action. It most often occurs in adult patients with both diabetes and CKD who have hyporeninemic hypoaldosteronism. Hyperkalemia is the most prominent electrolyte disturbance while the metabolic acidosis itself is usually mild.

SIADH occurs when the posterior pituitary gland or abnormal, unregulated sources such as lungs or tumors, secrete ADH despite the absence of physiological conditions that normally stimulate ADH secretion. The two usual stimuli for ADH release are elevated plasma osmolality and contraction of the effective arterial blood volume (eg, volume depletion,

congestive heart failure, cirrhosis). ADH primarily affects the collecting tubule and causes increased water reabsorption by increasing the permeability of the collecting duct by causing movement of aquaporins from intracellular lysosomes to the apical membranes. The hormonal effect of ADH augments normal free water retention, which subsequently leads to the main clinical manifestations of SIADH, namely, inappropriately concentrated urine (as reflected in a failure to decrease urine osmolality to 50–100 mOsm/kg) and hyponatremia in the setting of euvolemia. Although this manifestation most often occurs as a complication of intracranial lesions or from ectopic ADH production by a tumor or a diseased lung, many xenobiotics (eg, carbamazepine, chlorpropamide, antidepressants, vincristine, opioids, methylenedioxymethamphetamine {MDMA or Ecstasy}) can also cause inappropriate ADH release ([Chap. 19](#)).

Diabetes insipidus (DI) is the inability of the kidneys to maximally concentrate the urine and retain water leading to inappropriate loss of urine. Its two causes are the absence of pituitary ADH secretion (central DI) or by the absence of an appropriate renal response to ADH stimulation (nephrogenic DI). DI will typically present with polyuria or hypernatremia if water intake is limited, in the presence of inappropriately dilute urine. Central DI can be due to autoimmune destruction of the pituitary or trauma but often is the result of a space-occupying lesion affecting the posterior hypophysis. NDI can be caused by a variety of factors, including genetic disorders, kidney failure, disease states, or electrolyte perturbations, but xenobiotics are often implicated. Lithium, demeclocycline, foscarnet, and clozapine are drugs that can cause this syndrome ([Chap. 19](#)). NDI from lithium toxicity is thought to result from impaired aquaporin-2 synthesis and transport despite normal ADH binding to vasopressin type 2 receptors at the basolateral membranes of the collecting ducts.³⁸

PATIENT EVALUATION

Evaluation of a patient with suspected toxic renal injury should include consideration of extrarenal as well as renal factors. The kidney's response to xenobiotics is affected by baseline renal function, renal blood flow, and the presence of urinary tract obstruction, all of which must be considered.

History

A past history of renal disease or conditions that can affect the kidney (eg, diabetes, hypertension, cardiovascular disease, stones, urinary tract infection, prior chemotherapy) should be noted. Pertinent family history of kidney disease, glomerulopathy, kidney stones, and polycystic kidney disease needs to be recorded. Flank pain, hematuria, urine discoloration, or an abnormal pattern of urine output are important findings. Acute loss of kidney function may be suspected if urine output decreases, but oliguria is not universal. The patient's intravascular volume status affects renal perfusion. Thus, a recent history of heart disease, vomiting, or diarrhea is important. Symptoms of kidney failure are usually only present when severe but include anorexia, nausea and vomiting, leg cramps, fatigue, edema, and mental status changes. Systemic symptoms such as arthralgias, weight loss, and fever may suggest vasculitis.

All current xenobiotics should be evaluated for potential renal effects.¹⁵ The patient's intake of alcohol and drugs of abuse, as well intake of natural products and medicinal herbs, should be explored. A careful occupational history and assessment of hobbies and lifestyle are crucial, with emphasis on exposure to nephrotoxic xenobiotics.

Physical Examination

The patient's hemodynamic status should be carefully assessed. Postural changes in pulse and blood pressure, and either engorgement or decreased filling of the neck veins, give important information about the intravascular volume. The skin should be examined for lesions. Funduscopy may reveal evidence of chronic hypertension or diabetes. All aspects of cardiac function should be noted, including presence or absence of edema. Bluish discoloration of toes can suggest recent cholesterol emboli. Injuries or scars in the suprapubic area or evidence of past urologic or retroperitoneal surgery may suggest obstruction, as may a palpable or percussible bladder.

Laboratory Evaluation

Although history and physical examination may suggest nephrotoxic injury, laboratory testing is indispensable to confirm the degree of renal dysfunction. The approach to a patient with renal disease usually combines both assessment of GFR and urinalysis. Both are noninvasive, inexpensive, and have considerable predictive value for patients with renal disease.

Because creatinine is freely filtered by the glomerulus and not significantly reabsorbed or metabolized in the tubule, serum creatinine concentration is used as the preeminent marker of overall kidney function; because a small proportion of total excreted creatinine in urine appears as the result of tubular secretion, creatinine clearance always overestimates GFR. As the kidneys fail, creatinine concentration increases. However, the relationship between its concentration and GFR is hyperbolic, not linear; therefore, a small initial elevation in serum concentration denotes a large decrease in kidney function. By the time the serum creatinine concentration exceeds the upper limit of normal, GFR is reduced by up to 50%. Furthermore, creatinine secretion becomes a significantly greater proportion of creatinine excretion as GFR fails. Renal hypoperfusion and prerenal states are associated with a disproportionate rise in urea in comparison with the rise in

creatinine, because urea is partially reabsorbed in the proximal tubule along with salt and water. However, this often cited increase in the BUN–creatinine ratio may fail to occur in patients with chronic kidney disease, including the elderly. There are other limitations of their use as markers of renal injury; decreased production of urea (starvation or liver failure) or creatinine (amputation, muscle wasting) may result in a normal BUN or creatinine in the presence of significant renal impairment. Certain xenobiotics alter measured concentrations of urea and creatinine in the absence of any change in renal function.³² The most obvious is exogenous creatine taken to build muscle mass. Drugs that block renal creatinine secretion, such as cimetidine and trimethoprim, may also increase serum creatinine. BUN may be raised independently of renal function by corticosteroids (increased protein catabolism), tetracycline and by gastrointestinal bleeding due to digestion of hemoglobin.

Recently, more sensitive serum or urine markers of early AKI have been proposed, such as serum cystatin C, urinary kidney injury molecule-1, neutrophil gelatinase-associated lipocalin (NGAL), and N-acetyl- β -glucosaminidase. Early studies suggest they may help discriminate between ATN and prerenal AKI although they are costly and unavailable in most centers. Renal function can also be estimated by nuclear medicine and inulin clearance but these tests are impractical.

In patients with stable chronic kidney disease, a more precise estimation of the glomerular filtration rate is available. The Cockcroft-Gault formula and 24-hour urine collection for creatinine clearance are commonly used to assess renal function. More recently, the estimated GFR (eGFR) has been validated in several populations of kidney disease populations (Table 28–10). Using these measurements in AKI is not helpful, as the accuracy of the measurement of clearance implies a steady state. Changing GFR during a clearance time period distorts the resulting estimation. There is also a lag period between changes in kidney function and changes in BUN or creatinine concentrations. An extreme example would be a patient undergoing bilateral nephrectomy: although GFR immediately postoperatively equals 0 mL/min, the increase in serum creatinine will only be evident after a few hours. Any clearance calculation would yield an estimated GFR very different from true GFR. In general, a patient with AKI and rapidly changing creatinine concentration should be managed as if GFR were less than 10 mL/min until serum creatinine concentration stabilizes and GFR can more accurately be estimated. Estimation of GFR is most important in prescribing drugs. Since much of the relevant pharmacology literature predates the current equations used to estimate GFR, many recommendations for drug dosing are still based on the Cockcroft-Gault formula, which estimates creatinine clearance.

Most patients presenting with AKI should have their urine examined. Standard automated dipsticks will detect albumin and glucose. The presence of a positive dipstick for blood when the urine contains no or few RBCs suggests either rhabdomyolysis or hemolysis. A simple urine spot test may help discriminate prerenal azotemia from ATN (Table 28–6); this is suggested by a fractional sodium excretion below 1% and urine osmolality above 400 mOsm/kg. Direct microscopic examination of the urine sediment also provides useful clues. Dysmorphic red cells suggest glomerular hematuria but are neither sensitive nor specific. If acute interstitial nephritis is a consideration, a fresh urine sample should be stained for eosinophils.³¹ Crystalluria may suggest an obstructive cause to AKI and may reveal exposure to xenobiotics such as ethylene glycol.

Measurement of postvoiding residual urine volume, preferably by suprapubic ultrasonography or by passage of a urinary catheter with complete bladder emptying, can demonstrate lower urinary tract obstruction; if the volume is in excess of 75 to 100 mL, then bladder dysfunction or obstruction should be suspected. Among the many radiologic studies used in patients with kidney diseases, renal ultrasonography is the most useful and is indicated in all patients with AKI or CKD of unknown etiology; postrenal AKI is suggested by obstruction of the urinary tree, characteristically by swelling of one or two kidneys (hydronephrosis). Asymmetry between kidney diameters may suggest vascular stenosis. Cortex thinning and poorly differentiated corticomedullary junction are consistent with long-standing kidney failure of any etiology. When the etiology of kidney disease remains elusive, a percutaneous renal biopsy can establish the final diagnosis. Table 28–11 summarizes the nephrotoxic effect of various metals to demonstrate some of the complexities of the issue.

TABLE 28–11. Nephrotoxic Effects of Metals

	<i>Toxic ATN</i>	<i>Shock ATN</i>	<i>Hemolysis</i>	<i>Acute Interstitial Nephritis</i>	<i>Chronic Interstitial Nephritis</i>	<i>Tubular Dysfunction</i>	<i>Nephrotic Syndrome</i>
<i>Antimony</i>	+

<i>Thallium</i>	+			+			
<i>Uranium</i>	+						

+++ = common; + = uncommon. ATN = acute tubular necrosis.

SUMMARY

- The kidneys are exposed to exogenous or endogenous xenobiotics in their role as primary defenders against harmful xenobiotics entering the bloodstream.
- The environment, the workplace, and, especially, the administration of medications represent potential sources of nephrotoxicity. Consequently, it is important to determine, by history and observation, to which xenobiotics a patient may have been exposed and to be aware of their potential to harm the kidneys.
- It is equally crucial to work the other way when a patient presents with renal dysfunction: review all xenobiotics, both conventional and complementary, all xenobiotic exposures, and any conditions that can adversely affect the kidneys.

29 RESPIRATORY PRINCIPLES

Andrew Stolbach and Robert S. Hoffman

The primary function of the lungs is to exchange gases. Specifically, this involves the transport of oxygen (O_2) into the blood, and the elimination of carbon dioxide (CO_2) from the blood. In addition, the lungs serve as minor organs of metabolism and elimination for a number of xenobiotics, a source of insensible water loss, and a means of temperature regulation.

Cellular oxygen use is dependent on many factors, including respiratory drive; percent of oxygen in inspired air; airway patency; chest wall and pulmonary compliance; diffusing capacity; ventilation–perfusion mismatch; hemoglobin content; hemoglobin oxygen loading and unloading; cellular oxygen uptake; and cardiac output. Xenobiotics have the unique ability to impair each of these factors necessary for oxygen use and result in respiratory dysfunction. This chapter illustrates how xenobiotics interact with the mechanisms of gas exchange and oxygen use. Discussion of chronic occupational lung injury is beyond the scope of this text; the reader is referred to a number of reviews for further information.⁵

PULMONARY MANIFESTATIONS OF XENOBIOTIC EXPOSURES

Respiratory Drive

Respiratory rate and depth are regulated by the need to maintain a normal partial pressure of carbon dioxide (PCO_2) and pH. Most of the control for ventilation occurs at the level of the medulla, although it is modulated both by involuntary input from the pons and voluntary input from the higher cortices. Changes in PCO_2 are measured primarily by a central chemoreceptor, which measures cerebral spinal fluid pH, and secondarily by peripheral chemoreceptors in the carotid and aortic bodies, which measure PCO_2 . Input with regard to partial pressure of oxygen (PO_2) is obtained from carotid and aortic chemoreceptors. Stretch receptors in the chest relay information about pulmonary dynamics, such as the volume and pressure.

Xenobiotics can affect respiratory drive in one of several ways: direct suppression of the respiratory center; alteration in the response of chemoreceptors to changes in PCO_2 ; direct stimulation of the respiratory center; increase in metabolic demands such as those resulting from agitation or fever, which, in turn, increases total body oxygen consumption; or indirectly, as a result of the creation of acid–base disorders. For example, opioids ([Chap. 38](#)) depress respiration by decreasing the responsiveness of chemoreceptors to CO_2 and by direct suppression of the pontine and medullary respiratory centers.^{35,80,102} Any xenobiotic that causes a decreased respiratory drive or a decreased level of consciousness can produce bradypnea (a decreased respiratory rate), hypopnea (a decreased tidal volume), or both, resulting in hypoventilation ([Chap. 3](#)).

Methylxanthines and sympathomimetics may cause an increase in both respiratory drive and oxygen consumption. Salicylates produce hyperventilation by both central and peripheral effects via respiratory alkalosis and metabolic acidosis. The net consequence of increased respiratory drive, increased oxygen consumption, or metabolic acidosis is the generation of either tachypnea (an elevated respiratory rate), hyperpnea (an increased tidal volume), or both. Either alone or in combination, tachypnea and hyperpnea produce hyperventilation. [Tables 29–1 and 29–2](#) both list xenobiotics that commonly produce hypoventilation and hyperventilation.

Decreased Inspired FIO₂

Barometric pressure at sea level ranges near 760 mm Hg. At this pressure, 21% of ambient air is comprised of oxygen (the fraction of inspired oxygen {FiO₂} = 21%), and, after subtracting for the water vapor normally present in the lungs, the alveolar partial pressure of oxygen (PAO₂) is about 150 mm Hg. Any reduction in FiO₂ decreases the PAO₂, thereby producing signs and symptoms of hypoxemia (a low arterial partial pressure of oxygen {PaO₂}). At an FiO₂ of 12% to 16%, patients experience tachypnea, tachycardia, headache, mild confusion, and impaired coordination. A further decrease to an FiO₂ of 10% to 14% produces severe fatigue and cognitive impairment and when the FiO₂ decreases to between 6% and 10%, nausea, vomiting, and lethargy develop. An FiO₂ < 6% is incompatible with life.⁶³

This effect on PAO₂ is typically observed as elevation increases above sea level, because while FiO₂ remains 21%, barometric pressure falls. At 18,000 feet, barometric pressure is only 380 mm Hg, and the PAO₂ falls to below 70 mm Hg. At 63,000 feet, the barometric pressure falls to 47 mm Hg, a level where the PAO₂ equals 0 mm Hg. Although it is important to remember this relationship, altitude-induced decreases in PAO₂ are rarely important in clinical medicine, even in commercial airline flights, where the cabins are pressurized to a maximum of several thousand feet above sea level. However, in closed or low-lying spaces, oxygen may be replaced or displaced by other gases that have no intrinsic toxicity. Common examples of these gases, referred to as simple asphyxiants (Table 29–3), are found alone or in combination with more toxic gases. Because they have little or no toxicity other than their ability to replace oxygen, removal of the victim from exposure and administration of supplemental oxygen are curative if permanent injury as a consequence of hypoxia has not already developed (Chap. 124).

Methane

Nitrogen

Propane

The potential magnitude of toxicity from simple asphyxiants is best exemplified by disasters in Cameroon near Lake Mounoun and Lake Nyos, in 1984 and 1986, respectively. Following an earthquake, Lake Nyos, a volcanic lake, released a

cloud of CO₂ gas of approximately one quarter million tons. Because CO₂ is 1.5 times heavier than air, the gas cloud flowed into the surrounding low-lying valleys, killing by asphyxia more than 1700 people, and affecting countless more people because of hypoxia. Most survivors recovered without complications.^{11,39} Smaller scale, but equally serious, toxicity from CO₂ results from improper handling of dry ice or release into a closed space.^{40,45}

Chest Wall

Hypoventilation can result from a decrease in either respiratory rate or tidal volume. Thus, even when the stimulus to breathe is normal, adequate ventilation is dependent on the coordination and function of the muscles of the diaphragm and chest wall. Changes in this function can result in hypoventilation by two separate mechanisms; both muscle weakness and muscle rigidity may impair the patient’s ability to expand the chest wall. Some examples of toxicologic causes of muscle weakness include botulinum toxin,⁸⁷ electrolyte abnormalities, such as hypokalemia,^{57,103} or hypermagnesemia,^{2,32} organic phosphorus compounds,^{70,88} and neuromuscular blockers.^{14,50} Patients with hypoventilation caused by muscle weakness respond well to assisted ventilation and correction of the underlying problem (Chaps. 19, 41, 69, and 113). Chest-wall rigidity impairing ventilation can occur in strychnine poisoning,^{16,55,62} tetanus,^{23,55,93} and fentanyl use^{22,24} (Chaps. 38 and 117). Often these patients are difficult to ventilate despite tracheal intubation and may require muscle relaxants, neuromuscular blockers, or naloxone (for fentanyl).

Airway Patency

The airway may be compromised in several ways. As a patient’s mental status becomes impaired, the airway is often obstructed by the tongue.⁴² Alternatively, vomitus, or aspiration of activated charcoal or a foreign body, can directly obstruct the trachea or major bronchi with resultant hypoxia.^{52,65,83} Obstruction may also result from increased secretions produced during organic phosphorus compound poisoning. Laryngospasm may occur either as a manifestation of systemic reactions, such as anaphylaxis, as a result of edema from thermal or caustic injury (Chaps. 106 and 128), or as a direct response to an irritant gas (Chap. 124). Similarly, the tongue can become swollen in response to thermal or caustic injury or toxic exposure to plants such as *Dieffenbachia* spp, or as a result of angioedema from drugs such as angiotensin-converting enzyme inhibitors (Chaps. 63, 106, 121, and 128).³⁵ Regardless of the mechanism, upper airway obstruction results in hypoventilation, hypoxemia, and hypercapnia (hypercarbia) with the persistence of a normal alveolar–arterial (A–a) gradient (see discussion of A–a gradients). Upper airway obstruction is often acute and severe and requires immediate therapy to prevent further clinical compromise. Bronchospasm may be a manifestation of anaphylaxis, as well as exposure to pyrolyzed cocaine,⁸⁶ smoke, irritant gases⁴⁴ (Table 29–4), dust (eg, cotton in byssinosis), or as a result of work-related asthma⁶¹ and hypersensitivity pneumonitis¹⁰⁷ (Chaps. 124 and 128).

Sulfur dioxide

Airway collapse may result from pneumothorax caused by barotrauma, which more commonly results from the manner of administration of illicit xenobiotics than from actual drug overdose. Barotrauma may also result from nasal insufflation or inhalation of drugs. This form of barotrauma occurs most often in cocaine (particularly in the form of “crack”) and marijuana users, who either smoke or insufflate these xenobiotics and then perform prolonged Valsalva maneuvers in an attempt to enhance the effects of these xenobiotics (Chaps. 77 and 78).^{12,90,104} The increased airway pressure leads to rupture of an alveolar bleb, and free air dissects along the peribronchial paths into the mediastinum and pleural cavities. Nitrous oxide abuse also causes barotrauma.⁵³ Siphoning of nitrous oxide from low-pressure tanks meant for inhalation is

not typically associated with barotrauma. By contrast, inhalation of nitrous oxide, used as a propellant in whipped cream cans, generates tremendous pressure that sometimes results in severe barotrauma (Chaps. 68 and 84).

Ventilation–Perfusion Mismatch

Ventilation–perfusion (V/Q) mismatch is manifested at the extremes by aeration of the lung without arterial blood supply (as in pulmonary embolism from injected contaminants) and by a normal blood supply to the lung without any ventilation. Impaired blood supply to a normal lung and normal blood supply to an inadequately ventilated lung constitute an infinite number of gradations that exist between the extremes. The normal response to regional variations in ventilation is to shunt blood away from an area of lung poorly ventilated, thereby preferentially delivering blood to an area of the lung where gas exchange is more efficient. An hypoxia-induced reduction in local nitric oxide production appears to be responsible for the regional vasoconstriction that occurs.¹ This effect, commonly known as hypoxic pulmonary vasoconstriction, is best described in patients with chronic obstructive lung disease and facilitates compensation for the V/Q mismatch associated with that disorder. It is unclear whether xenobiotic-induced alterations in pulmonary nitric oxide production are significant determinants in the V/Q mismatch that occurs in poisoning.

In toxicology, V/Q mismatch most commonly results from perfusion of an abnormally ventilated lung, as may occur following aspiration of gastric contents, a frequent complication of many types of poisoning.^{52,71} Although alterations in consciousness and loss of protective airway reflexes are predisposing factors, certain xenobiotics, such as hydrocarbons, directly result in aspiration pneumonitis because of their specific characteristics of high volatility, low viscosity, and low surface tension (Chap. 108).

The diagnosis of aspiration pneumonitis often relies on chest radiography for confirmation. The location of the infiltrate depends on the patient's position when the aspiration occurred. Most commonly, aspiration occurs in the right mainstem bronchus, because the angle with the carina is not as acute as it is for entry into the left mainstem bronchus. When aspiration occurs in the supine position, the subsequent infiltrate is usually manifest in the posterior segments of the upper lobe and superior segments of the lower lobe. Aspiration typically involves vomitus; however, secretions, activated charcoal, teeth, dentures, food, and other foreign bodies are also frequently aspirated.

Diffusing Capacity Abnormalities

Severe impairment in diffusing capacity commonly results from local injury to the lungs in disorders such as interstitial pneumonia, aspiration, toxic inhalations, and near drowning, and from systemic effects of sepsis, trauma, and various other medical disorders.¹⁰ When this process is acute and associated with clinical criteria, including crackles, hypoxemia, and bilateral infiltrates on a chest radiograph demonstrating a normal heart size, it has been historically referred to as noncardiogenic pulmonary edema or, more recently, acute lung injury (ALI).¹⁰ The most severe manifestation of these processes was described as acute respiratory distress syndrome (ARDS). However, a task force of pulmonary specialists has determined that all of these conditions are best classified as gradations of ARDS. According to the 2012 Berlin definition, ARDS consists of bilateral pulmonary infiltrates (by radiography or computed tomography), which occur within 7 days of an inciting event and are not explained by heart failure or fluid overload. Severity of ARDS is determined by the $\text{PaO}_2/\text{FiO}_2$ ratio. ARDS may be classified as mild ($200 \text{ mm Hg} < \text{PaO}_2/\text{FiO}_2 \leq 300 \text{ mm Hg}$), moderate ($100 \text{ mm Hg} < \text{PaO}_2/\text{FiO}_2 \leq 200 \text{ mm Hg}$), and severe ($\text{PaO}_2 \leq 100 \text{ mm Hg}$). Cases that once were described as ALI may now fit under the mild ARDS classification.

Throughout this chapter and text, this newer nomenclature will be used. Using the older definition, it was estimated that approximately 150,000 Americans developed ARDS annually, many as a result of xenobiotics; severe ARDS has a fatality rate near 50%.^{4,34}

Commonly, patients are chronically exposed to xenobiotics associated with reduced diffusing capacity by smoking tobacco and other xenobiotics or working with asbestos, silica, and coal, which slowly causes pulmonary fibrosis or promotes emphysema. More recent work also emphasizes the ability of chronically smoked cocaine to alter pulmonary function.⁹⁴ Acutely, ARDS from opioids, salicylates, or phosgene and delayed severe fibrosis from paraquat can cause profound alterations in diffusion (Chaps. 38, 39, 112, and 132).^{76,84,108} Associated parenchymal damage is almost always present and causes both reduction in lung volumes and V/Q mismatch. Intravenous injection of talc, a common contaminant found in drugs of abuse,⁷⁸ and septic emboli from right-sided endocarditis^{77,92} may result in isolated vascular defects with reduction in diffusion capacity. Similarly, cocaine-induced pulmonary spasm can obstruct vascular channels and alter pulmonary function, creating V/Q mismatch.²⁸

ARDS commonly occurs in cases of poisoning. The edema fluid (and the resulting hypoxia, pulmonary crackles, and radiographic abnormalities) may develop in part because of increased permeability of the alveolar and capillary basement membrane.^{21,25,64,84} Proteinaceous fluid leaks from the capillaries into the alveoli and interstitium of the lung. Several mechanisms are proposed as the cause of ARDS, although no single unifying mechanism exists for all of the xenobiotics implicated. ARDS may result from exposure to xenobiotics that produce hypoventilation by at least three different

mechanisms: (1) hypoxia may injure the vascular endothelial cells, (2) autoregulatory vascular redistribution may cause localized capillary hypertension, or (3) alveolar microtrauma may occur as alveolar units collapse, only to be reopened suddenly during reventilation.⁸⁴ These and other events may activate neutrophils and release inflammatory cytokines.^{3,101} Other xenobiotics may be directly toxic to the capillary epithelial cells or may be partly responsible for the release of vasoactive substances.³ The effects of salicylates and other nonsteroidal antiinflammatory drugs may be mediated via effects on prostaglandin synthesis. Finally, sympathomimetic stimulants may cause “neurogenic” pulmonary edema, which may be mediated by massive catecholamine discharge. Elevated catecholamine concentrations are also noted in experimental opioid overdose, possibly representing support for a link between hypoxia, hypercarbia, and the catecholamine hypothesis of ARDS.⁶⁹

In the 1880s, William Osler described “oedema of left lung” in a morphine user. The opioids are still among the most common causes of ARDS ([Chap. 38](#)), but it is now recognized that there are many types of xenobiotics that can cause or are associated with ARDS, such as the sedative-hypnotics, salicylates, cocaine, carbon monoxide, diuretics, and calcium channel blockers ([Table 29–5](#)).^{29,31,33,37,38,43,46,49,56,79,81,91,92,108} The route of xenobiotic administration is not usually the determining factor; ARDS can result from oral, intravenous, and inhalational exposure. Because the source of the problem is increased pulmonary capillary permeability, patients with ARDS have a normal pulmonary-capillary wedge pressure, unlike patients with cardiogenic pulmonary edema.

Vinca alkaloids

Cardiogenic pulmonary edema may also occur as the result of poisoning. Etiologies for this phenomenon include the ingestion of large amounts of a xenobiotic with negative inotropy (eg, β -adrenergic antagonists, type 1A antidysrhythmics),

myocardial ischemia, or infarction (from cocaine). Because many overdoses are mixed overdoses, the distinction between cardiogenic pulmonary edema and ARDS is often difficult to establish by physical examination and requires invasive monitoring techniques.

Although the treatments for cardiogenic pulmonary edema and ARDS have many similarities, critical aspects of the therapy differ; therefore, an accurate diagnosis must be established. Most diagnostic tests are not helpful in differentiating between the two diseases. Physical examination reveals the presence of crackles with both entities. An S₃ gallop, if present, suggests a cardiac cause, but its absence does not establish the diagnosis of ARDS. In both entities, the arterial blood–gas analysis demonstrates hypoxia and chest radiography shows perihilar, basilar, or diffuse alveolar infiltrates. However, the presence of “vascular redistribution” on chest radiography is suggestive of a cardiogenic etiology; a normal-sized heart is more commonly associated with ARDS, whereas an enlarged heart is more typical of cardiogenic pulmonary edema. The diagnostic tests that may be useful in establishing the correct diagnosis include echocardiography, transcutaneous bioimpedance, pulmonary artery catheter pressure measurements, and radionuclide ventriculography (“gated-pool” scan). Although the radionuclide scan accurately measures cardiac output, it is not routinely available in the emergency department or intensive care unit and usually requires the transport of a critically ill patient to the nuclear medicine suite. Although echocardiography can be performed as a portable “bedside” technique, it is less sensitive and less specific for determinations of cardiac output. Therefore, the most definitive diagnostic procedure in the emergency setting is the insertion of a pulmonary artery catheter for hemodynamic monitoring. Cardiogenic pulmonary edema results from an elevated left-atrial filling pressure (elevated pulmonary-capillary wedge pressure) and a decreased cardiac output. In patients with ARDS, the pulmonary artery wedge pressure and the cardiac output are normal. Although not specifically well investigated in poisoning, experiences with transcutaneous bioimpedance measurements of cardiac output show promise for this portable noninvasive technique.^{10,26,68,72}

The basic treatment for ARDS is supportive care while the xenobiotic is eliminated and healing occurs in the pulmonary capillaries.^{3,59} The most important specific therapeutic maneuver in patients with ARDS requiring mechanical ventilation involves the use of low tidal-volume ventilation (≤ 6 mL/kg predicted body weight).^{1,41,101}

This results in reduced airway pressures, which seem to decrease the chance for alveolar distension and subsequent injury. The efficacy of jet ventilators or membrane oxygenators is inadequately studied. Some studies suggested a potential role for extracorporeal membrane oxygenation in the treatment of ARDS.⁵⁴ Positive end-expiratory pressure (PEEP), which may derive its benefit from keeping alveoli open, is considered an essential component in the management of ARDS.^{30,41}

PEEP should be maintained in the range of 5 to 12 cm H₂O, to maintain a PO₂ of at least 55 mm Hg, or an oxygen saturation of 88%, with an inspired oxygen concentration of $\leq 40\%$. Higher PEEP settings are not always beneficial and can cause an increased incidence of pneumothorax or hypotension. An increase in PEEP may result in a modest increase in PO₂, but a larger decrease in venous return and decreased cardiac output. Therefore, with each change in PEEP, the resulting increase (or perhaps decrease) in oxygen delivery to the body should be determined.⁴

A conservative fluid strategy improves oxygenation and decreases stays in the intensive care unit without increasing the incidence of shock or the need for hemodialysis. A conservative fluid management strategy is recommended for patients with ARDS not in shock, have not been in shock for at least 12 hours, and do not have other reasons to require liberal fluid administration.⁷⁴

Hemoglobin and Chemical Asphyxiants

Disorders of hemoglobin oxygen content, and of hemoglobin loading and unloading, result in cellular hypoxia, which, in turn, results in hyperventilation. Anemia is a common complication of the infectious diseases associated with injection drug use. In addition, many xenobiotics result in hemolysis or direct bone marrow suppression. Among the latter group are the metals, lead, benzene, and ethanol. Hemolysis may occur in individuals exposed to lead, copper, or arsine gas, and in patients with glucose-6-phosphate dehydrogenase deficiency exposed to oxidants (Chap. 22).

The oxygen-carrying capacity of blood declines in almost direct proportion to hemoglobin content,⁹⁶ as seen in Fig. 29–1. As shown in Fig. 29–1A, under most normal conditions the dissolved oxygen content of the blood contributes little; thus, the last portion of the equation can be eliminated. Anemia resulting in a decrease of the hemoglobin content to 7.5 g/dL (a hematocrit of $\sim 22\%$) decreases the oxygen content of the blood to about 10.2 mL O₂/dL (Fig. 29–1B). Because central cyanosis is only visible with a concentration of reduced deoxyhemoglobin of at least 5 g/dL, unless an abnormal hemoglobin concentration is present, anemia can significantly impair oxygen-carrying capacity without the development of this common physical manifestation (Chap. 127).

Oxygen content (O_2 content) = hemoglobin bound oxygen + dissolved oxygen

A. Normal conditions: hemoglobin (Hb) = 15 g/dL; PO_2 = 100 mm Hg,

oxygen saturation (O_2 sat) = 95%

$$\begin{aligned} O_2 \text{ content} &= [(Hb)(O_2 \text{ sat}) (\text{constant}) + (\text{another constant})(PO_2)] \\ &= [(Hb)(O_2 \text{ sat})(1.39 \text{ mL } O_2/\text{g}\%) \\ &\quad + (0.003 \text{ mL } O_2/\text{dL/mm Hg})(PO_2)] \\ &= [(15 \text{ g/dL})(95\%)(1.39 \text{ mL } O_2/\text{g}\%) \\ &\quad + (0.003 \text{ mL } O_2/\text{dL/mm Hg})(100 \text{ mm Hg})] \\ &= [(19.8 \text{ mL } O_2/\text{dL}) + (0.3 \text{ mL } O_2/\text{dL})] \\ &= \mathbf{20.1 \text{ mL } O_2/\text{dL} = 20.1 \text{ vol}\%} \end{aligned}$$

B. Anemia: Hb = 7.5 g/dL; PO_2 = 100 mm Hg, O_2 Sat = 95%

$$\begin{aligned} O_2 \text{ content} &= [(Hb)(O_2 \text{ sat})(1.39 \text{ mL } O_2/\text{g}\%) \\ &\quad + (0.003 \text{ mL } O_2/\text{dL/mm Hg})(PO_2)] \\ &= [(7.5 \text{ g/dL})(95\%)(1.39 \text{ mL } O_2/\text{g}\%) \\ &\quad + (0.003 \text{ mL } O_2/\text{dL/mm Hg})(100 \text{ mm Hg})] \\ &= [(9.9 \text{ mL } O_2/\text{dL}) + (0.3 \text{ mL } O_2/\text{dL})] \\ &= \mathbf{10.2 \text{ mL } O_2/\text{dL} = 10.2 \text{ vol}\%} \end{aligned}$$

C. Hyperbaric oxygen: Hb = 15 g/dL; PO_2 = 1500 mm Hg, O_2 Sat = 100%

$$\begin{aligned} O_2 \text{ content} &= [(Hb)(O_2 \text{ sat})(1.39 \text{ mL } O_2/\text{g}\%) \\ &\quad + (0.003 \text{ mL } O_2/\text{dL/mm Hg})(PO_2)] \\ &= [(15 \text{ g/dL})(100\%)(1.39 \text{ mL } O_2/\text{g}\%) \\ &\quad + (0.003 \text{ mL } O_2/\text{dL/mm Hg})(1500 \text{ mm Hg})] \\ &= [(20.9 \text{ mL } O_2/\text{dL}) + (4.5 \text{ mL } O_2/\text{dL})] \\ &= \mathbf{25.4 \text{ mL } O_2/\text{dL} = 25.4 \text{ vol}\%} \end{aligned}$$

FIGURE 29–1. Examples of calculations of the oxygen content of the blood under various conditions.

By contrast, as the PO_2 reaches higher values (as in hyperbaric oxygen chambers), the dissolved oxygen content becomes significant and may be of therapeutic value, particularly when the oxygen-carrying content of hemoglobin is compromised. The PO_2 corresponding to an FiO_2 of 100% at 1 atm is approximately 575 mm Hg. By contrast, with hyperbaric oxygen at 3 atm and 100% oxygen, PO_2 values in excess of 1500 mm Hg can be achieved.⁶³ Under these conditions, the dissolved oxygen content of the blood rises dramatically (to as much as 4.5 mL O_2 /dL) and may be adequate to sustain life, even in the absence of any contribution from hemoglobin (Fig. 29–1C).

The chemical asphyxiants that produce methemoglobin, carboxyhemoglobin, and sulfhemoglobin interfere with oxygen loading and/or unloading to various degrees. Methemoglobin inhibits oxygen loading, producing cyanosis unresponsive to supplemental oxygen (Chap. 127). In addition, the oxyhemoglobin saturation curve is shifted to the left, interfering with unloading (Fig. 29–2). Carboxyhemoglobin has similar effects on oxygen loading and unloading, but carboxyhemoglobin is not associated with cyanosis (Chap. 125). While sulfhemoglobin also impairs oxygen loading, it shifts the oxyhemoglobin saturation curve to the right, favoring unloading of the remaining normal hemoglobin. Cyanide, hydrogen sulfide, and sodium azide primarily affect oxygen use by interfering with the cytochrome oxidase system (Chap. 126).

FIGURE 29–2. Oxyhemoglobin dissociation curve at 98.6°F (37°C) and pH 7.40. Hematocrit does not alter this relationship.

Cardiac Output

Any xenobiotic that causes a decreased cardiac output or hypotension may result in tissue hypoxia and tachypnea. This occurs most frequently with overdoses of β -adrenergic antagonists and calcium channel blockers, antidysrhythmics, cyclic antidepressants, and phenothiazines ([Chap. 17](#)).

Asthma and Occupational Exposures

Usually considered a cause of morbidity more than mortality, work-related asthma is frequently encountered by the practitioner. The pathophysiology of these illnesses is still being elucidated, and appears to result from both immunoglobulin (Ig) E and non-IgE-related mechanisms.¹⁵

Work-related asthma can be divided into three distinct clinical entities:

1. Work-aggravated asthma: Preexisting asthma worsened by allergens in the workplace.
2. Occupational asthma: Asthma caused by workplace exposure and not factors outside the workplace. There is a latency period between the symptoms and the first exposure, possibly as long as several years.
3. Reactive airway dysfunction syndrome (RADS): Asthma caused by nonimmunogenic stimuli in the workplace, occurring for the first time within 24 hours of exposure to an inhaled irritant xenobiotic.^{6,20,100}

Occupational exposures are thought to be responsible for a substantial proportion of adult-onset asthma, estimated at 10% to 25% in one international prospective study.¹⁹

A large number of xenobiotics and occupations are associated with the development of work-aggravated and work-related asthma. Because researchers rely on surveys and interviews, the latency period between exposure and symptoms makes identification of these associations a challenge.

Many high molecular weight xenobiotics, usually plant or animal derived, are known etiologies, such as arthropod and mite-related materials, latex, flour, molds, endotoxins, and biological enzymes. Lower molecular weight xenobiotics associated with work-related asthma include isocyanates (used in spray paints and foam manufacturing), cleaning agents, anhydrides, amines, dyes, and glues. For more information on specific xenobiotics, see [Chap. 124](#).

In one study, the following occupations were found, in decreasing order, to be associated with the development of occupational asthma: printing, woodworking, nursing, agriculture and forestry, cleaning and caretaking, and electrical processors.⁵⁸

By contrast to occupational asthma and work-related asthma, the latency period between exposure and symptoms in RADS is short or absent, so the health care professional may more easily identify the precipitant from history. Xenobiotics frequently associated with RADS include cleaning materials (including chlorine, hypochlorite, ammonia, and chloramines), solvents, toluene diisocyanate, acids, alkali, nitrogen oxides, smoke, and diesel exhaust.^{47,89}

APPROACH TO THE POISONED PATIENT

The initial assessment of each patient must involve the evaluation of upper airway patency. Adequacy of ventilation should

then be determined. If concomitant injury is suspected, then care must be taken to protect the cervical spine. When airway patency is in question, maneuvers to establish and protect the airway are of prime importance. Often this may simply involve repositioning the chin, jaw, or head, or suctioning secretions or vomitus from the airway. However, insertion of an oral or nasopharyngeal airway, or nasopharyngeal or endotracheal intubation, or surgical cricothyroidotomy may be required as clinically indicated. After the airway is secured, high-flow supplemental oxygen if needed should be provided and the depth, rate, and rhythm of respirations evaluated. An acceptable tidal breath is one that transports 10 to 15 mL of air/kg of body weight.⁴

Hypoventilation that results from an inadequate respiratory rate or tidal volume is arbitrarily defined as a PCO_2 higher than 44 mm Hg and leads to hypoxia and ventilatory failure if uncorrected.¹⁰⁵ The symptoms of hypoxia and or hypercarbia are nonspecific and resemble toxicity from many xenobiotics. Initially, patients appear restless and confused. Signs of sympathetic discharge, such as tachycardia and diaphoresis, may be noted. Later, patients may complain of headache, only to become sedated and subsequently comatose, as further deterioration occurs. These signs and symptoms are often nonspecific. We recommend early determination of oxygenation and ventilation when there is concern for respiratory failure in patients following xenobiotic overdose. Arterial blood gas or pulse oximetry may be used to identify hypoxia, while capnography or blood gas (venous or arterial) are good modalities for determining ventilation.

A trial of naloxone, hypertonic dextrose, and thiamine may be indicated for the patient with an altered mental status and or respiratory compromise ([Chap. 4](#)). Because opioid overdose and hypoglycemia are rapidly reversible, potential causes of respiratory failure, these diagnoses should be addressed before most other interventions are considered. Failure to identify and reverse these conditions may result in unnecessary diagnostic and therapeutic interventions in addition to irreversible neurologic sequelae.

Having assured an acceptable airway, the remainder of the evaluation can proceed. A rapid assessment of the remainder of the vital signs ([Chap. 3](#)) should then occur. Obtaining a history and physical examination, measured oxygen saturation, measured ventilation, and chest radiography are sufficient to determine the diagnosis of pulmonary pathology in most cases. However, adjuncts, such as measurement of negative inspiratory force (NIF), invasive hemodynamic monitoring, evaluation of the arterial–venous oxygen difference, xenon ventilation and technetium scanning, and computed tomographic scanning may be required.

History

A directed history must include questions on the nature, onset, and duration of symptoms; substance use and abuse; home and occupational exposures; and underlying pulmonary pathology. If the patient has a significant degree of respiratory compromise, most or all of the history may have to be obtained from friends, relatives, paramedics, coworkers, or others.

Physical Examination

The physical evaluation must include a detailed assessment of depth, rate, and rhythm of respirations, use of accessory muscles, direct evaluation of the oropharynx, position of the trachea, and presence and quality of breathing sounds. Skin, nail bed, and conjunctival color must be observed for pallor or cyanosis. Funduscopic examination is a useful adjunct to the examination. Papilledema may be noted in the presence of acute hypercapnia. Additionally, because cyanide poisoning interferes with oxygen delivery to tissue, the venous oxygen saturation remains high. During the funduscopic examination, this may appear as arteriolization of the retinal veins, where the veins take on a color more characteristic of arteries ([Chap. 126](#)). A general assessment of muscle tone, with a specific emphasis on ocular and neck muscles, may give clues to flaccidity or rigidity syndromes that interfere with respiration. When in doubt, a determination of the negative inspiratory force will provide a rapid, objective, quantifiable bedside assessment of respiratory strength.

Pulse Oximetry

Pulse oximeters have gained widespread acceptance as rapid, noninvasive indicators of hemoglobin oxygen saturation. As defined, hemoglobin oxygen saturation is the ratio of oxyhemoglobin to total hemoglobin. By using two light-emitting diodes, the pulse oximeter is able to measure absorbance at the peak wavelengths for oxyhemoglobin and deoxyhemoglobin (typically at 940 and 660 nm). Thus, the ratio of oxyhemoglobin to oxyhemoglobin plus deoxyhemoglobin (total hemoglobin) can be calculated. The clinician may then estimate the PO_2 from the oxygen saturation.

Limitations of this approach require elaboration. Because the oxyhemoglobin saturation curve becomes quite flat above 90% saturation ([Fig. 29–2](#)), small changes in saturation greater than 90% may represent very large changes in PO_2 . Thus, a decrease from 97% saturation to 95% saturation may represent a substantial decrease in PO_2 . Although a low saturation is an early indicator of hypoxic hypoxia, this is only one of many causes of tissue hypoxia. If total hemoglobin is low, then oxygen-carrying capacity is inadequate even with excellent saturation ([Fig. 29–1](#)). Dyshemoglobinemias, such as carboxyhemoglobin, methemoglobin, and possibly sulfhemoglobin, interfere with the accuracy of pulse oximeter determinations and are of particular concern in the poisoned patient. Specifically, using a standard pulse oximeter, the

presence of elevated concentrations of methemoglobin will tend to make the saturation approach 84% to 86% (Chap. 127).^{8,77} Carboxyhemoglobin is falsely interpreted by the pulse oximeter as mostly oxyhemoglobin, thus readings tend to appear normal even with significant carbon monoxide poisoning (Table 29–6).⁹⁷ Accurate response by the pulse oximeter also requires adequate blood pressure, lack of strong venous pulsations (as might occur in a patient with tricuspid regurgitation), translucent nails (some shades of nail polish may interfere), absence of circulating dyes (methylene blue), and a near-normal temperature. If the pulse oximeter does not produce an accurate reading, then arterial blood gas may be obtained to assess oxygenation. Finally, we are often more interested in PCO₂ than PO₂, which is not a direct measure of ventilation. The pulse oximeter gives no information with regard to PCO₂. Although the pulse oximeter may give early clues to the presence of hypoxic hypoxia, extrapolation of oxygen saturation to standard arterial blood–gas values may be difficult because of the many possible sources of error.

TABLE 29–6. Sample Interpretations of Oxygen Saturations Reported by Various Sources of Measurement

Condition	Percent Oxygen Saturation			
	PO ₂ (mm Hg)	Arterial Blood Gas	Pulse Oximeter	Cooximeter
Normal	95	95	95	95
Anemia	95	95	95	95*
Methemoglobinemia (30%)	95	95	85	70
Carboxyhemoglobinemia (30%)	95	95	95	70
Hypoxemia	60	90	90	90

The table demonstrates limitations of the various methods for determining oxygen saturation (O₂ saturation). The arterial blood gas calculates the O₂ saturation from the dissolved oxygen content (PO₂) and becomes abnormal only when the PO₂ falls. The pulse oximeter uses only two wavelengths of light and produces substantial errors in the presence of a dyshemoglobinemia. Because the cooximeter uses more wavelengths of light than the pulse oximeter, it can correctly identify the presence of carboxyhemoglobin and methemoglobin. The cooximeter has the additional advantage (*) of calculating the total hemoglobin and oxygen content, so that it is useful in the setting of anemia. All techniques are acceptable for the assessment of hypoxemia.

Pulse–cooximeters (noninvasive spectral analysis cooximeter), designed to measure carboxyhemoglobin and methemoglobin, in addition to hemoglobin oxygen saturation, are entering clinical practice. Use of these devices can potentially facilitate early, noninvasive diagnosis of carbon monoxide poisoning and methemoglobinemia, as well as minimize erroneous interpretations of standard pulse oximetry caused by the presence of these abnormal hemoglobins. A volunteer study, sponsored by the manufacturer of the device, demonstrated the ability to measure carboxyhemoglobin with an uncertainty of $\pm 2\%$ within the range of 0% to 15% and methemoglobin with an uncertainty of 0.5% within the range of 0% to 12%.⁷ In a large study of screening for carboxyhemoglobin, the noninvasive cooximeter was 94% sensitive (95% confidence interval {CI}: 71%–100%) and 77% specific (95% CI: 75%–79%) for identification of a carboxyhemoglobin rate above 6.6%.⁸⁵ Other authors have found high rates of false negatives when using the noninvasive cooximeter to screen for carbon monoxide poisoning.⁹⁵

Because of these limitations, the best role for this device is as a rapid screening tool. Positive results should be confirmed with a blood carboxyhemoglobin concentration, as should normal results whenever carbon monoxide poisoning is highly suspected, or when the result from the machine is not consistent with the clinical appearance of the patient.

Capnography

Capnography is the noninvasive measurement of PCO₂ from the airway. Both the numerical value of CO₂ and the shape of the tracing, the capnogram, provide information to the clinician (Fig. 29–3). Measurements are obtained constantly during inhalation and exhalation. End-tidal CO₂ (EtCO₂) is the maximum partial pressure of CO₂ at the end of exhalation. EtCO₂ underestimates PaCO₂ because exhaled air consists mostly of CO₂–poor air from dead space, in addition to air expired from alveoli. Anatomic dead space, always present, is from the nonventilated upper airways, whereas physiologic dead space results from underperfused areas of the lung. Therefore, a high EtCO₂ always correlates with an elevated PaCO₂, whereas a low value may be spurious. In patients without pulmonary disease, EtCO₂ is 2 to 5 mm Hg less than PaCO₂.⁷³ In nonintubated emergency department patients with metabolic acidosis, the mean difference was 6 mm Hg.⁹ EtCO₂ can be

used to confirm endotracheal intubation, monitor endotracheal tube placement, monitor patients during procedural sedation, and assess patients with pulmonary illness. EtCO₂ has been used as a tool to assess ventilation in patients obtunded from a xenobiotic (Fig. 29–3).²⁷

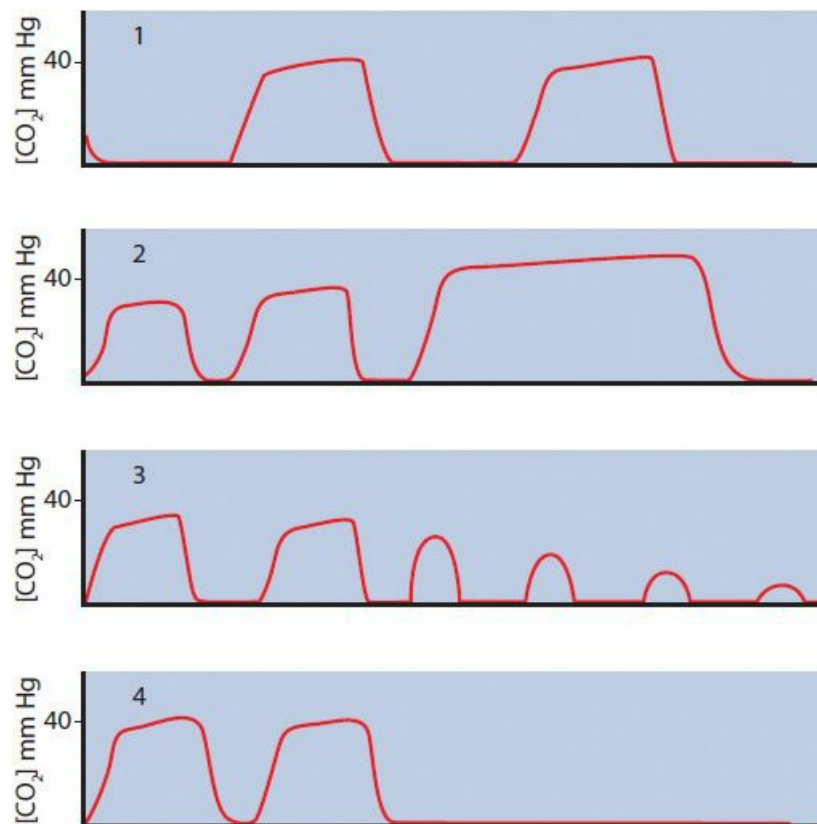

FIGURE 29–3. Capnograms. (1) Normal capnogram. (2) Bradypnea and hypoventilation. The tidal volumes are the same as (1) but the rate is slowing down. (3) Hypopnea and hypoventilation. The amplitude of the waveforms is decreasing. (4) Complete laryngospasm or apnea. After initial waveforms, there is no expired CO₂.

Blood–Gas Analysis

Arterial blood–gas analysis is an easy and rapid means of evaluating both acid–base status and gas exchange. Attention must be paid to the method for determining oxygen saturation, specifically whether it is measured or calculated from the PO₂. If the measured O₂ saturation is lower than would be predicted from the PO₂ (the calculated O₂ saturation), then the presence of an abnormal hemoglobin concentration (such as carboxyhemoglobin or methemoglobin) must be suspected. A normal calculated O₂ saturation does not exclude these disorders (see Use of the Cooximeter).

Because it is easier to obtain, venous blood–gas analysis is often used as a substitute for arterial blood–gas analysis.¹⁷ In comparison with arterial values, venous pH and PO₂ are lower, whereas PCO₂ is higher. Errors can be introduced by increased muscle activity of the extremity being tested (eg, seizures.) In most cases, a venous blood gas can be used to evaluate PCO₂ and pH, but not PO₂. However, mixed venous blood (defined as right-heart blood) is required for accurate determination of the arterial–venous oxygen extraction and is an excellent indicator of acid–base status, cardiovascular function, and oxygen use. Unfortunately, a central venous catheter is required for sampling. When performing a peripheral venous blood–gas analysis, it is usually assumed that this is only an approximation of mixed venous blood.

The arterial PO₂ is generally considered adequate only if it lies within the flat portion at the upper right of the sigmoidal-shaped oxyhemoglobin dissociation curve (Fig. 29–2). That portion of the curve includes the PO₂ range from 60 to 100 mm Hg, which corresponds to oxygen saturations higher than 90%. As mentioned earlier, within this flat portion there can be discernible changes in PO₂ with little change in oxygen saturation. For instance, an arterial PO₂ of 80 mm Hg corresponds roughly to an oxygen saturation of 95%. If the PO₂ falls to 60 mm Hg, then the oxygen saturation falls to 90%. This insignificant decrease in the oxygen-carrying capacity of the blood is of minimal clinical concern. However, if the PO₂ falls another 20 mm Hg, then there is a more significant reduction in oxygen saturation, to approximately 70%. Thus, changes in PO₂ higher than 60 mm Hg are usually not of acute therapeutic significance, because the O₂ saturation is higher than 90%. However, these changes are frequently of diagnostic significance.

An exception to this concept applies to the patient who is under metabolic stress, as might result from low cardiac output, impaired vascular flow, anemia, or dyshemoglobinemia. Under these circumstances even the modest gain achieved by increasing both dissolved oxygen content and hemoglobin saturation higher than 90% may be desirable, as discussed

earlier (see Hemoglobin and Chemical Asphyxiants). Also, even if a PO_2 higher than 60 mm Hg or an O_2 saturation higher than 90% is considered acceptable in most acute settings, it is still desirable to achieve greater values, when feasible, to create a safety zone in case of clinical deterioration.

Significance of a Decreased PO_2

In a patient with a diminished PO_2 , five clinically relevant mechanisms for the hypoxemia should be considered: (1) alveolar hypoventilation, (2) V/Q mismatch, (3) shunting, (4) diffusion abnormality, and, rarely, (5) a decrease in FiO_2 . In most clinical circumstances, diffusion defects cannot be distinguished from V/Q mismatch. Usually the responsible mechanism can be identified by calculating the A–a oxygen gradient. In patients with alveolar hypoventilation, the A–a gradient is completely normal (≤ 15 mm Hg when breathing room air). Patients with V/Q mismatch have an A–a gradient that is increased but which normalizes when 100% oxygen is administered for at least 20 minutes. A normal A–a gradient is defined as less than 100 mm Hg on 100% oxygen. The arterial PO_2 on 100% oxygen reaches approximately 575 mm Hg. By contrast, a patient with a shunt will also have an increased A–a gradient while breathing room air, but when 100% oxygen is administered, the arterial PO_2 falls to substantially less than 575 mm Hg and the A–a gradient does not normalize. Finally, in the case of a patient with hypoxia resulting from breathing in an environment in which the FiO_2 is less than 21%, the PO_2 should correct rapidly when the patient is removed from the environment or supplemental oxygen is delivered.

In general, a low PO_2 can be improved by supplying supplemental oxygen. Although in this instance the patient's laboratory values may be corrected, the underlying process persists. It is important to remember that the laboratory correlate of hypoventilation is hypercapnia on the arterial blood–gas analysis. If hypercapnia is associated with acidemia, then assisted ventilation should be considered, regardless of whether the PO_2 corrects with supplemental oxygen.

Use of the Cooximeter

Routine analysis of an arterial blood gas yields a measured pH, a measured PO_2 , and a measured PCO_2 . Ordinarily, the serum bicarbonate, base excess, and percent oxygen saturation of hemoglobin are all calculated values. The oxygen saturation is of clinical significance because it usually correlates with the oxygen content of the blood; thus, the oxygen available to the tissues. However, implied in this relationship is a normal amount of functional hemoglobin. Because the oxygen saturation is calculated from the measured PO_2 using the oxyhemoglobin dissociation curve, it represents only the saturation of normal hemoglobin. Thus, in the presence of even a small percentage of abnormal hemoglobin, the calculated oxygen saturation overestimates the total oxygen content of the blood. For example, a patient with PO_2 of 95 mm Hg has a calculated oxygen saturation of 95%. If the patient also has a 30% methemoglobinemia, only 70% of the total hemoglobin is saturated to 95% and the actual saturation is only 67%. This gap is clinically important because hemoglobin saturations of less than 90% do not provide adequate oxygen delivery to the tissues.

As discussed above, despite the development of bedside noninvasive pulse-cooximetry, most clinicians still depend on laboratory cooximeters for measurement of carboxyhemoglobin and methemoglobin. Most cooximeters spectrophotometrically measure total hemoglobin, oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin. Newer models measure fetal hemoglobin and sulfhemoglobin as well (Fig. 29–4). The resultant saturation is a measured oxygen saturation of the total hemoglobin by including four common hemoglobin variants, and thus correlates with the total oxygen content of the blood.

FIGURE 29–4. Cooximetry curves for normal and abnormal hemoglobin variants. Transmitted light absorbance spectra are shown for four hemoglobin species: oxyhemoglobin, reduced (deoxy) hemoglobin, carboxyhemoglobin, and methemoglobin.

The difference between measured and calculated oxygen saturation represents the percentage of abnormal hemoglobin present. This gap is helpful in the diagnosis of methemoglobin and carboxyhemoglobin, and is useful in assessing the adequacy of therapy for these disorders. Common indications for cooximetry include cyanosis that is unresponsive to oxygen (methemoglobin and sulfhemoglobin), known use of methemoglobin-forming xenobiotics (such as dapsone), smoke inhalation (carboxyhemoglobin and possibly methemoglobin), and evaluation of therapy for cyanide toxicity (methemoglobin).

Like so many other tools, the cooximeter is not perfect. Its biggest limitation occurs when dealing with uncommon hemoglobins. Older cooximeters use four wavelengths of light and have the ability to define only four hemoglobin variants. Consequently, rare dyshemoglobinemias, such as sulfhemoglobin, have been interpreted as one or a combination of the four common hemoglobin variants, giving erroneous results. This phenomenon is commonly noted in neonates in whom fetal hemoglobin may be interpreted as carboxyhemoglobin.^{99,106} Although this error rarely adds greater than 10% to the true carboxyhemoglobin value, this amount can be significant because of the difficulties in assessing the neuropsychiatric status of infants possibly exposed to carbon monoxide. Newer cooximeters use at least six wavelengths of light and are designed to measure fetal hemoglobin and sulfhemoglobin directly, avoiding these interference problems.⁵¹ Another source of interference with cooximetry has been the use of hydroxocobalamin, which has a deep red color. Hydroxocobalamin administration has resulted in falsely low carboxyhemoglobin by laboratory cooximetry.⁶⁶ Clinicians should use caution in interpreting carboxyhemoglobin concentrations in patients who have received hydroxocobalamin. When available, a sample obtained before hydroxocobalamin administration should be sent for cooximeter analysis.

Additionally, cooximeters tend to inconsistently interpret low levels (< 2.5%) of carboxyhemoglobin.⁶⁷ Fortunately, this rarely has clinical implications.

Chest Radiography

Radiographic detection of a pneumothorax or pneumomediastinum, cardiogenic pulmonary edema, ARDS, aspiration pneumonia, or the presence of a foreign body is crucial, but can usually be delayed until the initial evaluation is completed. Confirmation of endotracheal tube placement is necessary but initially can be ascertained by auscultating bilateral breath sounds following compression of a bag valve mask, or using a variety of marketed devices such as EtCO₂ detectors designed to help confirm tube placement. For patients with occupational disorders, chest radiography is essential to confirm and stage exposures to asbestos, silica, coal, and other causes of pneumoconiosis.

THERAPEUTIC OPTIONS

Supplemental Oxygen

Supplemental oxygen is indicated for all patients with suspected or confirmed respiratory insufficiency. Although it is generally advisable to begin with high flow (12 L/min) via a nonrebreather mask, lower concentrations of oxygen can be used in more stable patients. Supplemental oxygen can be titrated lower to the minimum flow rate required to achieve adequate oxygen saturation. Pulse oximetry is a good modality for monitoring oxygenation especially if used in conjunction with EtCO₂ recognizing the limitations of both modalities. The clinician may opt to obtain either a venous or an arterial blood gas if there is concern that pulse oximetry saturation and the EtCO₂ are not reflective of the true saturation.

Hyperbaric oxygen is indicated for carbon monoxide poisoning and rarely other exposures (Antidotes in Depth: A38).

Initially, there should be limited concern over worsening hypercapnia in patients with chronic obstructive pulmonary disease and respiratory failure. This concern should not deter clinicians from providing needed oxygen, because many of these patients will require intubation for their hypoventilation. It is important to appreciate that supplemental oxygen will improve hypoxia but not hypercarbia.

Additional respiratory support can be offered from bilevel positive airway pressure (BiPAP). Some experimental evidence supports the use of BiPAP for patients with acute respiratory dysfunction in the emergency department.⁸² Although this technique may be useful in overdosed patients, it should be considered only as a temporizing measure for patients who are expected to recover rapidly, or while preparing for intubation.

Intubation

After the decision for mechanical ventilation has been made, the route needs to be selected. The editors of this text prefer oral intubation because it permits the use of a larger endotracheal tube—usually 8 mm or even larger in adults—than does nasal intubation. If the patient later needs bronchoscopy, then it can be performed through the endotracheal tube. Some data

suggest that bronchoscopy with bronchoalveolar lavage may be of both diagnostic⁹⁸ and therapeutic⁶⁰ benefit for selected poisoned patients. However, in a patient who is awake, nasotracheal intubation done blindly or with the aid of a flexible fiberoptic laryngoscope may be more easily performed. Newer fiberoptic devices facilitate oral intubation in difficult cases making nasotracheal intubation almost obsolete. An advantage of nasotracheal intubation over oral intubation is that orogastric lavage can be performed more easily when the oral cavity is unimpeded. After the trachea is intubated, the tube should be checked to ensure that it is correctly positioned.

All patients who sustain overdoses and show signs or symptoms of respiratory insufficiency should have chest radiography performed. Unfortunately, intubated patients usually have portable radiography performed and the carina may be difficult to visualize because of the poor quality of the study. When seen, the carina is visualized between T-5 and T-7 in most patients. Thus, the tip of the endotracheal tube should be above T-5 for proper (safe) placement. When portable chest radiography is obtained, the patient's neck may be extended or flexed, altering the location of the endotracheal tube tip. For this reason it is essential to note the position of the neck during radiography, because the tip of the endotracheal tube may move up (with flexion) or down (with extension) by almost 2 cm.¹³

Mechanical Ventilation

After a patient is intubated for ventilatory support, the respirator mode is selected. Patients with pure hypoventilation usually require a controlled fixed rate that can be easily adjusted based on pulse oximetry, EtCO₂ and or serial venous or arterial blood–gas analyses. Patients with pulmonary parenchymal processes, such as ARDS or pneumonia, usually do best when placed on either assist control (AC) or intermittent mechanical ventilation (IMV) mode. Both of these modes are volume-controlled, meaning the clinicians set a volume and a minimal rate. In each of these modes the patient may take additional breaths. In AC, the additional patient breaths trigger a ventilator-delivered breath at the preset tidal volume. With the IMV mode, the tidal volume of extra patient-initiated breaths is determined by the patient. This may permit lower mean airway pressure, which theoretically may reduce the risk of barotrauma and hemodynamic compromise. Although the lower airway pressures associated with IMV are desirable, many authorities recommend the use of the assist mode because it eliminates the patient's work of breathing.⁵⁹

The next step is to determine the appropriate FiO₂ to be delivered to the patient. A number of formulas have been devised. One simple approach is to intubate a patient, control breathing, administer 100% oxygen, and decrease to an FiO₂ of less than 50% as quickly as possible in an attempt to prevent oxygen toxicity.³ Although the toxic effects of oxygen are well known for paraquat ([Chap. 112](#)), evidence suggests that oxygen may be an important mediator of other xenobiotic-induced pulmonary injuries such as with iron.⁴⁸ A PO₂ of 55 mm Hg or a measured oxygen saturation > 88% is generally acceptable; thus, there is little reason to expose patients to much higher concentrations of oxygen once these conditions are met.^{1,101} Many clinicians feel more comfortable establishing a “buffer” against deterioration by increasing the PO₂ to somewhat greater than 55 mm Hg, but prolonged exposure to higher values is rarely indicated. Tidal volumes should be set on the order of 6 mL/kg/breath. These lower, “protective” tidal volumes cause less barotrauma, lung injury, and cytokine release. Lower tidal volumes decrease mortality and ventilator days for patients with ARDS and to improve clinical outcomes in patients without ARDS.^{1,75} If oxygenation cannot be maintained with FiO₂ at or less than 50%, PEEP may be used, with careful reassessment of serial arterial blood–gas analyses, changes in effective compliance, and hemodynamic data with each increment in PEEP.

Pharmacologic Interventions: Antidotes

Only a few antidotes have a significant role in reversing xenobiotic-induced respiratory dysfunction. Naloxone may have the greatest role. Atropine and pralidoxime may be useful for respiratory dysfunction from cholinesterase inhibitors (Antidotes in Depth: A32 and A33, and [Chap. 113](#)). Elapid antivenom and botulinum antitoxin are rarely used but may be lifesaving. Neostigmine can reverse muscle weakness from nondepolarizing neuromuscular blockers ([Chap. 69](#)). More commonly, clinicians are required to treat bronchospasm from exposure to pulmonary irritants. The use of β_2 -selective adrenergic-agonist bronchodilators are effective in these patients.³⁶ The role of corticosteroids remains controversial.³

When treating patients with bronchospasm from one of the work-related asthma syndromes, it is reasonable that management should be similar to that of any patient with pulmonary bronchospasm, ie, emphasizing inhaled bronchodilators and corticosteroids ([Fig. 29–5](#)).

Two 30 year old patients who overdosed were brought to the ED. Each had ingested substantial amounts of barbiturates and diazepam. An arterial blood gas drawn from patient 1 while he was breathing room air revealed a pH of 7.18, PCO_2 of 70 mm Hg, PO_2 of 50 mm Hg, and a calculated bicarbonate of 24 mEq/L. An arterial blood gas drawn from patient 2, also breathing room air, revealed a pH of 7.31 PCO_2 of 50 mm Hg, PO_2 of 50 mm Hg, and a calculated bicarbonate of 25 mEq/L. Quick analysis showed that patient 1 was hypercapnic with a significant respiratory acidosis. Patient 2 did not appear as ill; his PCO_2 was not very elevated and his pH was not significantly reduced. The A-a gradients were calculated to be 12.5 mm Hg for patient 1 and 37.5 mm Hg for patient 2.

A. Arterial PCO_2 approximates alveolar PCO_2 and is substituted as:

$$\text{PAO}_2 = \text{PIO}_2 - \frac{\text{PCO}_2}{R}$$

$$\text{PIO}_2 = (\text{FIO}_2)(\text{PB} - \text{PH}_2\text{O})$$

where PAO_2 is alveolar PO_2 , PIO_2 is partial pressure of inspired O_2 , PaCO_2 is arterial PCO_2 , and R is the respiratory exchange ratio. Therefore:

$$\text{PAO}_2 = [(\text{FIO}_2)(\text{PB} - \text{PH}_2\text{O})] - \frac{\text{PCO}_2}{R}$$

where FIO_2 is the inspired O_2 fraction PH_2O is water vapor pressure, and PB is barometric pressure. On room air at sea level, $\text{FIO}_2 = 21\%$. At steady state, $R = 0.8$. At sea level, $\text{PB} = 760$ mm Hg, and $\text{PH}_2\text{O} = 47$ mm Hg. Therefore:

$$\text{PAO}_2 = [(\text{FIO}_2)(\text{PB} - \text{PH}_2\text{O})] - \frac{\text{PCO}_2}{R}$$

$$= [(0.21)(760 - 47)] - \frac{\text{PCO}_2}{R}$$

$$= 150 - [(1.25)(\text{PCO}_2)]$$

Because the A-a gradient is equal to $\text{PAO}_2 - \text{PaO}_2$, it can be expressed as:

$$150 - [(1.25)(\text{PCO}_2)] - \text{PaO}_2 \text{ or } 150 - [(1.25)(\text{PCO}_2) + \text{PaO}_2]$$

A normal A-a gradient on room air is 10–15 mm Hg, but this increases with age. A rough estimate of the normal A-a gradient is one-third the patient's age.

B. Referring to the two overdosed patients above, the A-a gradient for patient 1 is:

$$150 - [(1.25)(70) + 50] = 12.5 \text{ mm Hg}$$

This calculation reveals a normal gradient, indicating that the etiology for hypoxemia and hypoventilation is extrinsic to the lung itself. In patient 2, the A-a gradient is:

$$150 - [(1.25)(50) + 50] = 37.5 \text{ mm Hg}$$

This abnormally high A-a gradient is consistent with the aspiration which was pneumonia seen on the patient's chest radiograph.

FIGURE 29–5. (A) Derivation of the definition of alveolar–arterial (A–a) oxygen gradients. (B) Using the A–a gradients

An inhaled solution of 2% sodium bicarbonate may provide symptomatic relief for patients with pulmonary exposure to hydrogen chloride or to chlorine (Antidotes in Depth: A5).

Exogenous nitric oxide has been considered for a variety of pulmonary conditions. Specifically, nitric oxide may be useful as a bronchodilator,¹⁸ a means to reverse hypoxic pulmonary vasoconstriction,³ and as treatment for ARDS.² Unfortunately, controlled studies fail to demonstrate a benefit for nitric oxide in patients with ARDS.^{3,101} Similarly, the results are disappointing for corticosteroids, surfactants, and a variety of antiinflammatory agents.^{4,101}

SUMMARY

- Xenobiotics may adversely affect tissue oxygenation at every step required for ventilation, oxygen delivery, and cellular respiration.
- Hypoxia and hypercarbia should be addressed as soon as they are suspected clinically. The use of supplemental oxygen or assisted ventilation should not be delayed.
- Although the clinical manifestations of hypoxia are constant regardless of etiology, the history, physical examination, and diagnostic testing often help to identify the specific mechanism of hypoxia.
- Invasive and noninvasive measures of oxygenation and ventilation may be used to assess response to therapy and need for further therapy. Clinicians should familiarize themselves with the strengths and limitations of pulse oximetry, end-tidal carbon dioxide capnography, venous and arterial blood-gas analyses, and cooximetry.
- In most cases of xenobiotic-induced respiratory depression, general supportive measures are favored over specific antidotal therapy.

30 THERMOREGULATORY PRINCIPLES

Susi U. Vassallo and Kathleen A. Delaney

Despite exposure to wide fluctuations of environmental temperatures, human body temperature is maintained within a narrow range.^{17,126} Elevation or depression of body temperature occurs when (1) thermoregulatory mechanisms are overwhelmed by exposure to extremes of environmental heat or cold; (2) endogenous heat production is either inadequate, resulting in hypothermia, or exceeds the physiologic capacity for dissipation, resulting in hyperthermia; or (3) disease processes or xenobiotic effects interfere with normal thermoregulatory responses to heat or cold exposure.

METHODS OF HEAT TRANSFER

Heat is transferred to or away from the body through radiation, conduction, convection, and evaporation. Radiation involves the transfer of heat from a body to the environment and from warm objects in the environment, for example, from the sun to a body. Conduction involves the transfer of heat to solid or liquid media in direct contact with the body. Water immersion conducts significant amounts of heat away from the body. This effect facilitates cooling in a swimming pool on a hot summer day or may lead to hypothermia despite moderate ambient temperatures on a rainy day. The amount of heat lost through conduction and radiation depends on the temperature gradient between the skin and its surroundings; cutaneous blood flow; and insulation such as subcutaneous fat, hair, clothing, or fur in lower animals.¹⁴³ In the respiratory tract, heat is lost by conduction to water vapor or gas. In animals unable to sweat, this represents the primary method of heat loss. The amount of heat lost through the respiratory tract depends on the temperature gradient between inspired air and the environment and the rate and depth of breathing.¹⁴³ Convection is the transfer of heat to the air surrounding the body. Wind velocity and ambient air temperature are the major determinants of convective heat loss. Evaporation is the process of vaporization of water, or sweat. Large amounts of heat are dissipated from the skin during this process, resulting in cooling. Ambient temperature, rate of sweating, air velocity, and relative humidity are important factors in determining how much heat is lost through evaporation. On a very hot and humid day, sweat may pour off an exercising person who rather than evaporating and initiating heat loss is accomplishing little heat loss. In very warm environments, thermal gradients may be reversed, leading to transfer of heat to the body by radiation, conduction, or convection.¹⁵⁶

PHYSIOLOGY OF THERMOREGULATION

In a normal human, stimulation of peripheral and hypothalamic temperature-sensitive neurons results in autonomic, somatic, and behavioral responses that lead to the dissipation or conservation of heat. Thermoregulation is the complex physiologic process that serves to maintain hypothalamic temperature within a narrow range of $98.6 \pm 0.8^{\circ}\text{F}$ ($37 \pm 0.4^{\circ}\text{C}$), known as the set point.¹²⁶ This hypothalamic set point is influenced by factors such as diurnal variation, the menstrual cycle, and others. Maintaining, raising, or lowering the set point results in many outwardly visible physiologic manifestations of thermoregulation such as sweating, shivering, flushing, or panting. In the central nervous system (CNS), thermosensitive neurons are located predominantly in the preoptic area of the anterior hypothalamus, but to a lesser extent in the posterior hypothalamus. These neurons may be divided into those that are warm sensitive, cold sensitive, or temperature insensitive. Approximately 30% of preoptic neurons are warm sensitive. These increase their firing rate during warming and decrease their firing rate during cooling.³⁰ Warming of the hypothalamus in conscious animals results in vasodilation, hyperventilation, salivation, and increases in evaporative water loss, as well as a reduction of cold-induced shivering and vasoconstriction.¹²⁶ Cooling of the hypothalamus in conscious animals causes shivering, vasoconstriction, and increased metabolic rate even if the environment is hot.¹¹⁷ How these temperature-sensitive neurons of the hypothalamus detect temperature changes and effect neuronal transmission is unclear. Altered action potential initiation and propagation caused by temperature-dependent membrane potential changes associated with the ratios of Na^{+} to Ca^{2+} ions that alter neuronal excitability and neurotransmitter release, or effects on the $\text{Na}^{+}\text{-K}^{+}\text{-ATPase}$ (adenosine triphosphatase) pump.¹⁴³ Xenobiotics that increase intracellular cyclic adenosine monophosphate (cAMP) concentrations increase the thermosensitivity of warm-sensitive neurons.³⁰ In the brainstem, warm- and cold-sensitive neurons are located in the medullary reticular formation, where information from cutaneous receptors, spinal cord, and preoptic area of the anterior hypothalamus is integrated.¹³²

The spinal cord is thermosensitive. Heat and cold sensitive ascending spinal impulses are conducted in the spinothalamic tract. As in the hypothalamus, local heating or cooling of the spinal cord results in thermoregulatory responses.¹²⁶ In addition to the hypothalamus, brainstem, and spinal cord, there is evidence of thermosensitivity in the deep abdominal viscera.^{113,126,228} Intraabdominal heating or cooling results in thermoregulatory responses. Cold and warm sensitive afferent impulses can be recorded from the splanchnic nerves in animals.^{113,230} Finally, the skin also contains heat and cold thermosensitive neurons. Whereas cold receptors are free nerve endings that protrude into the basal epidermis, warm sensitive receptors protrude into the dermis.^{125,127} Cutaneous thermoreceptor output is affected by the absolute temperature of the skin, rate of temperature change, and area of stimulation.¹²⁶ Cutaneous cold receptors are A- δ and C nociceptor afferent fibers. A δ fibers are small-diameter, thinly myelinated fibers that conduct at 5 to 30 m/sec, and C fibers are small-diameter, unmyelinated fibers that conduct at 0.5 to 2 m/sec.¹²¹ Afferents from heat receptors are primarily C fibers. Cutaneous thermoreceptive neurons respond to external temperature change as well as rate of temperature change, sending early warning to the CNS via afferent impulses, allowing rapid and transient thermoregulatory responses before brain temperature changes (Fig. 30–1).

FIGURE 30–1. A representation of the response of cutaneous thermoreceptive neurons to external temperature change as an early warning to the central nervous system.

Vasomotor and Sweat Gland Function

Vasomotor responses to thermoregulatory input differ according to location. The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. Increased body-core temperature results in active vasodilation in the extremities and is under noradrenergic control; increasing sympathetic stimulation results in vasoconstriction, and decreasing sympathetic control results in vasodilation. Vasodilation in the head, trunk, and proximal limbs is not a result of decreased sympathetic tone; instead, it is a result of an active process that is under the influence of cholinergic sudomotor nerves and local effects of temperature on vasomotor tone. Sweat glands release local transmitters, such as vasoactive intestinal polypeptide (VIP) or bradykinins, and vasodilation results. Areas of the body such as the forehead, where sweating is most prominent during heat stress, correspond to areas where active vasodilation is greatest. The neurotransmitters involved in the regulation of relationships between vasodilation and sweating as a response to heat stress are not fully elucidated, but animal evidence suggests the presence of specific vasodilator nerves.¹²⁶

Sweat glands are controlled by postganglionic nerve fibers, which are cholinergic, and large amounts of acetylcholinesterase as well as other peptides are involved in neural transmission.^{125,126}

Neurotransmitters and Thermoregulation

The neurotransmitters involved in thermoregulation include serotonin, norepinephrine, acetylcholine, dopamine, prostaglandins, β -endorphins, and intrinsic hypothalamic peptides such as arginine vasopressin, adrenocorticotrophic

hormone, thyrotropin-releasing hormone, and melanocyte–stimulating hormone.^{51,217} Studies on the effects of individual neurotransmitters in thermoregulation yield contradictory results, depending on the animal species and the route of administration of the exogenous neurotransmitter. Refinements in techniques of microinjection of neurotransmitters into the hypothalamus of animals, rather than intraventricular instillation, have elucidated microanatomic sites where neurotransmitters are active. More research is needed, however, because interspecies variations and theoretical differences in response to exogenous versus endogenous peptides make this area of study complex.

Apomorphine is a mixed dopamine agonist that causes hypothermia in animals; studies using selective D₁- and D₂-receptor agonists and antagonists suggest that the hypothermic effect of apomorphine is a result of its effects on D₂ receptors, with some modulation by D₁ receptors in the hypothalamus.¹⁹⁵ Stimulation of D₂ receptors appears to mediate the hypothermia induced by the peptide sauvagine.³³ Stimulation of D₃ by specific agonists caused hypothermia in an animal model.^{196,197} There appears to be a link between dopamine D₂ receptors and norepinephrine receptors in the hypothalamus, perhaps leading to vasodilation and hypothermia. The effect of clozapine in producing hypothermia in rats is caused by D₁ and D₃ stimulation.^{196,241} Lesser known peptides appear to be involved in thermoregulation. For example, neuropeptide Y is an amino acid neurotransmitter that occurs in high concentrations in the preoptic area of the anterior hypothalamus. Administration of neuropeptide Y caused a reduction in core temperature when administered with adrenergic receptor antagonists such as prazosin, an α_1 -adrenergic antagonist; propranolol, a β -adrenergic antagonist; and clonidine, a central α_2 -adrenergic agonist.^{84,239} Studies on muscarinic receptors suggest the involvement of muscarinic M₂ and M₃ receptors in the production of hypothermia when agonists to these receptors are administered centrally.²⁴² Blockers of ATP–sensitive K⁺ channels can reverse the effect of cholinomimetic drugs in producing hypothermia.²²⁵

DRUG EFFECTS ON THERMOREGULATION

Many xenobiotics have pharmacologic effects that interfere with thermoregulatory responses (Tables 30–1 and 30–2).^{180,182,281} α -Adrenergic agonists prevent vasodilation in response to heat stress. Increased endogenous heat production in the setting of increased motor activity also occurs in patients poisoned with cocaine or amphetamines. Life-threatening hyperthermia is associated with the use of these xenobiotics. Whereas adrenergic antagonists and calcium channel blockers diminish the cardiac reserve available to compensate for heat-induced vasodilation, diuretics decrease cardiac reserve through their effects on intravascular volume.⁶⁴ β -Adrenergic antagonists also interfere with the capacity to maintain normothermia under conditions of cold stress, possibly related to their interference with the mobilization of substrates required for thermogenesis.^{126,182} Opioids and diverse sedative–hypnotics depress hypothalamic function and predispose to hypothermia in the overdose setting.⁸⁶ Carbon monoxide poisoning must also be considered in hypothermic patients. Organic phosphorous insecticides and other xenobiotics that cause cholinergic stimulation cause hypothermia by stimulation of inappropriate sweating and possibly through depression of the endogenous use of calorogenic substrates.¹⁸² Xenobiotics with anticholinergic effects decrease sweating and predispose to hyperthermia during environmental heat exposure or exercise. Phenothiazines appear to interfere with normal response to both heat and cold. Severe hyperthermia associated with the absence of sweating is frequently described in patients using phenothiazines and may be a consequence of their anticholinergic effects.^{243,297} Effects on cold tolerance are attributed to their α -adrenergic antagonist effects, which prevent vasoconstriction in response to cold stress.¹⁸¹ In addition, hyperthermia associated with severe extrapyramidal rigidity may occur in patients taking antipsychotics.¹⁷³ This rigidity is attributed to the dopamine-blocking effects of this class of drugs.

TABLE 30–1. Effects of Xenobiotics That Predispose to Hyperthermia

I. Impaired cutaneous heat loss

- A. Vasoconstriction through α -adrenergic stimulation
 - Amphetamines
 - Cocaine
 - Ephedrine
 - Phenylpropanolamine
 - Pseudoephedrine
- B. Sweat gland dysfunction
 - Antihistamines
 - Belladonna alkaloids

Cyclic antidepressants
Topiramate
Zonisamide

II. Myocardial depression

- A. Decreased cardiac output
 - Antidysrhythmics
 - β -Adrenergic antagonists
 - Calcium channel blockers
- B. Reduced cardiac filling by salt and water depletion
 - Diuretics
 - Ethanol

III. Hypothalamic depression

Antipsychotics

IV. Impaired behavioral response

Cocaine
Ethanol
Opioids
Phencyclidine
Sedative–hypnotics

V. Uncoupling of oxidative phosphorylation

Dinitrophenol
Pentachlorophenol
Salicylates

VI. Increased muscle activity through agitation, seizures, or rigidity

Amphetamines
Caffeine
Cocaine
Isoniazid
Lithium
Monoamine oxidase inhibitors
Phencyclidine
Strychnine

VII. Dystonia

Butyrophenones
Phenothiazines

VIII. Withdrawal

Dopamine agonists
Ethanol
Sedative–hypnotics

α -Adrenergic antagonists

Ethanol

Phenothiazines

Ethanol is the xenobiotic most commonly related to the occurrence of hypothermia in an urban setting.^{62,288,289} The mechanism by which ethanol predisposes to hypothermia is said to be by virtue of its effects on CNS depression, vasodilation, and blunting of behavioral responses to cold. However, thermoregulatory dysfunction associated with ethanol intoxication is undoubtedly more complex.

In animal models, ethanol leads to hypothermia, the extent of which is partly dependent on ambient temperature.^{211,231,232} In mice, as the dose of ethanol increased, body temperature decreased, and the rate of this decline in body temperature was faster at higher ethanol doses.²⁰⁶ The decline in body temperature could be reversed by increasing ambient temperature; increasing ambient temperature to 96.8°F (36°C) caused an immediate rise in the body temperature.²⁰⁶ The poikilothermic effect of ethanol was not a result of hypoglycemia. Poikilothermia is the variation in body temperature greater than $\pm 3.6^\circ\text{F}$ ($\pm 2^\circ\text{C}$) on exposure to environmental temperature changes. Rats treated with equipotent amounts of sodium pentobarbital showed the same effects on body temperature as rats treated with ethanol, suggesting a similar central mechanism of CNS depression resulting in altered thermoregulation.²⁰⁶

Numerous mechanisms are involved in the ethanol-induced depression of CNS function.²³⁶ Genetic factors influence the role of ethanol in the production of hypothermia. Mice can be selectively bred for genetic sensitivity or insensitivity to acute ethanol-induced hypothermia, and the differences appear to be mediated by the serotonergic systems.^{87,101,200,206} Cyclo His-Pro DKP, another neurotransmitter that is found in many animal species, acts at the preoptic-anterior hypothalamus to modulate body temperature.^{41,136} Exogenous administration of this neuropeptide produced a dose-dependent decrease in ethanol-induced hypothermia. Attenuation of hypothermia resulted from passive immunization with CHP antibody.^{41,136} Ethanol effects may be mediated through modulation of endogenous opioid peptides because high-dose (10 mg/kg) naloxone reverses ethanol-induced hypothermia in animals.²²¹

Pharmacokinetic characteristics of ethanol metabolism change in the presence of hypothermia. Hypothermic piglets

infused with ethanol showed slower ethanol metabolism and a smaller volume of distribution (Vd) and, as a result, higher ethanol concentrations than normothermic control piglets. Ethanol elimination and metabolism decreased as temperature fell.¹⁶³

Tolerance develops to the effect of ethanol in producing hypothermia in all species.^{89,211} The degree of tolerance is proportional to the dose and duration of treatment with ethanol and is not explained by the increased rate of metabolism with chronic exposure.¹⁴³ Age is a factor in the development of tolerance; older animals do not display the same degree of tolerance to the hypothermic effects of chronic ethanol administration as do younger animals.^{203,220,296} The development of tolerance to ethanol-induced hypothermia is affected by genetic factors. Experimentally, tolerance to ethanol-induced hypothermia increases the incorporation of certain amino acids into proteins in the rat brain. The formation of new proteins in ethanol-tolerant rats suggests stimulation of gene expression related to the tolerant state.^{143,284} Deficits in N-methyl-D-aspartate (NMDA) receptor systems may also be implicated in the development of ethanol tolerance. In addition, altered nicotinamide adenine dinucleotide (NADH) oxidation to NAD⁺, diminished blood flow to the liver, or slowing of metabolism through the microsomal enzyme system may be involved.²³⁶

Hypothermia alters the breath-ethanol partition in the alveolus, and the temperature of expired breath alters breath-ethanol analysis results. In patients with mild hypothermia, ethanol-breath analysis results in lower values by 7.3% per degree centigrade (or 1.8°F) decrease in body temperature.⁹² Whether breath-ethanol analysis is also affected by hyperthermia remains to be studied.⁹²

DISEASE PROCESSES AND THERMOREGULATION

Many disease processes interfere with normal thermoregulation, limiting an individual's capacity to prevent hypothermia or hyperthermia. Extensive dermatologic disease or cutaneous burns impair sweating and vasomotor responses to heat stress.³⁶ Patients with autonomic disturbances such as diabetes mellitus or peripheral vascular disease also have altered vasomotor responses that impair vasodilation and sweating.²²⁹ Extensive surgical dressings may preclude the evaporation of sweat in an otherwise normal patient. Heat stressed persons with poor cardiac reserve may not be able to sustain skin blood flow rates high enough to maintain normothermia.^{76,264} Intense motor activity may lead to excessive heat production in patients with Parkinson disease or hyperthyroidism. Patients with agitated delirium or seizures also have significantly elevated rates of endogenous heat production. Hypothalamic injury caused by cerebrovascular accidents, trauma, or infection may disturb thermoregulation.^{75,177} Hypothalamic dysfunction can lead to high, unremitting fevers and insufficient stimulation of heat loss mechanisms such as sweating. Hypothalamic damage may predispose to hypothermia by interference with centrally mediated heat conservation.^{75,177,244,245} Fever, the normal response to stimulation of the hypothalamus by pyrogens, results in an elevated physiologic temperature set point and is a disadvantage in the heat-stressed individual.¹²⁶

HYPOTHERMIA

Epidemiology

Hypothermia is defined as a lowering of the core body temperature to below 95°F (<35°C). Between 1999 and 2002, 4607 people had hypothermia-related diagnoses listed on their death certificates as the underlying cause of death.⁴⁶ Most of these, 2622, were caused by exposure to excessive cold; in the remainder, hypothermia resulted from some reason other than exposure, such as medical illness^{43,44,130,159} (Table 30–3).

Social isolation

Uremia

Most hypothermic deaths occur in the winter months; however, mildly cool environments and windy wet conditions are also frequently associated with hypothermia. From 1999 to 2011, a total of 16,911 deaths in the United States were associated with exposure to excessive natural cold. Alaska, Montana, Wyoming, and New Mexico had the greatest overall death rates from hypothermia. States with milder climates and rapid fluctuations in temperature, such as North and South Carolina, and western states, such as Arizona, with high elevations and cold nighttime temperatures, report hypothermia-related deaths.⁴⁶

Response to Cold

The normal physiologic response to cold is initiated by stimulation of cold-sensitive neurons in the skin, so that the onset of the body response to cold occurs before cooling of central blood. Cold-sensitive neurons in the skin send afferent impulses to the hypothalamus, resulting in shivering and piloerection. Shivering is the main thermoregulatory response to cold in humans, except in neonates, in whom nonshivering thermogenesis prevails. Shivering is initiated in the posterior hypothalamus when impulses from cold-sensitive thermoreceptors are integrated in the anterior hypothalamus and communicated to the posterior hypothalamus or when cold-sensitive neurons in the posterior hypothalamus are activated directly. Efferent stimuli from the posterior hypothalamus travel through the midbrain tegmentum, pons, and lateral medullary reticular formation to the motor pathways of the tectospinal and rubrospinal tracts, resulting in shivering.²² A mechanism of stimulation of shivering that usually occurs later when core temperature drops is the local cooling of the spinal cord, which leads to shivering by increasing excitability of motor neurons.

Heat produced without muscle contraction is known as nonshivering thermogenesis.^{34,126} Nonshivering thermogenesis is mediated by the sympathetic nervous system.⁵⁶ Catecholamines activate adenylate cyclase, increasing cAMP, resulting in mobilization of fat and glucose stores (β -adrenergic receptors).^{183,238} Nonshivering thermogenesis is blocked by α -adrenergic receptor antagonism and increased by administration of norepinephrine. Brown adipose tissue is the most important site of nonshivering thermogenesis. In humans, brown fat is found primarily in neonates, although in cold-acclimatized people, there may be small amounts found on autopsy.³⁴ Brown adipose tissue functions as a thermoregulatory effector organ, producing heat by the oxidation of fatty acids when the tissue is stimulated by norepinephrine.⁴⁰

In addition to shivering and nonshivering thermogenesis, efferent sympathetic fibers from the hypothalamus stimulate peripheral vasoconstriction (α -adrenergic receptors). Piloerection and vasoconstriction result in decreased heat loss from the body. Intense vasoconstriction shunts blood away from the periphery to the core and antidiuretic hormone antagonism results in increased urine output and hemoconcentration.

Several disease processes commonly result in an inability to maintain a normal body temperature in a cool environment (Table 30–3). Hypothermia may develop in association with sepsis, hypothyroidism, hypoglycemia, uremia, hepatic failure, or poor nutrition.^{68,175} Hypothalamic injury may result in chronic poikilothermia.¹⁸¹ Thiamine deficiency adversely affects the hypothalamus, perhaps because of inefficient glucose metabolism, and leads to hypothermia.¹⁶¹ Spinal cord transection above the first thoracic segment interrupts hypothalamic–sympathetic outflow pathways, resulting in hypothermia.²²⁹ Frail elderly adults are at greater risk of hypothermia because of decreased vasomotor responses and a decreased capacity to shiver.^{56,59} Mentally and physically compromised patients may be unable to make appropriate behavioral responses to hot or cold environments.

Evaluations to determine the presence of underlying diseases are often difficult in a patient with hypothermia.^{90,175} The mental status may be markedly altered by hypothermia but is not usually abnormal until the temperature falls below 90°F (32.2°C). If normal mental status is not regained when the temperature reaches 90°F (32.2°C) during rewarming, underlying CNS structural, toxic, or metabolic problems must be considered.^{90,175,226} Failure of the patient to rewarm quickly suggests the presence of underlying disease⁶⁸ (Fig. 30–2). In one study, whereas hypothermic patients without underlying disease are reported to rewarm at a rate of 1.0 to 3.7°F/h (0.6–2.1°C/h) (average, 2.1°F/h; 1.2°C/h), patients with significant underlying disease (sepsis, gastrointestinal {GI} hemorrhage, diabetic ketoacidosis, pulmonary embolus, myocardial infarction) warmed at a rate of 0.25 to 1.8°F/h (0.1–1.0°C/h) (average, 1°F/h; 0.6°C/h).²⁸⁸

(Reproduced with permission from Delaney KA, Vassallo SU, Larkin GL, et al. Rewarming rates in urban patients with hypothermia: prediction of underlying infection. *Academic emergency medicine: official journal of the Society for Academic Emergency Medicine*. 2006;Sep;13(9):913–921.)

Alteration of Pharmacology in Hypothermia

The pharmacology of certain xenobiotics is altered in the setting of hypothermia. In hypothermic piglets, the V_d and the clearance of fentanyl are decreased.¹⁶³ Similarly, in piglets given gentamicin, the V_d and clearance rate decreased in direct proportion to the decrease in cardiac output and glomerular filtration rate (GFR).¹⁶² Hypothermic puppies given intravenous (IV) lidocaine showed slower rates of disappearance of the drug than when normothermic.²⁰¹ Humans and animals given propranolol showed a reduced V_d and decreased total body clearance, resulting in higher than expected propranolol concentrations.^{35,188,189,209} Decreased hepatic metabolism of propranolol during hypothermia has been shown in vitro.¹⁸⁹ Hypothermia prolongs neuromuscular blockade with d-tubocurarine¹¹⁵ and increases neuromuscular blockade with suxamethonium.²⁹³ Phenobarbital metabolism and V_d decreased with hypothermia in children.¹⁴² The lethal dose of digoxin was doubled in hypothermic dogs.¹⁸ Digoxinlike substances are present during hypothermia.^{97,129}

Reasons for altered metabolism in hypothermia include delayed distribution of the drug and altered enzyme function with temperature and pH changes. Cardiac output decreases, leading to decreased liver perfusion and decreased delivery of drug to hepatic microsomal enzymes.^{115,145–147,218} Plasma volume decreases as free water moves intracellularly, causing hemoconcentration and further decreasing organ perfusion.¹¹⁶ Biliary excretion of atropine, procaine, and sulfanilamide decreases in vitro.^{145–147} The GFR decreases in hypothermia.³¹ In vitro, the activity of metabolic pathways, including acetylation and hydrolysis, decrease with cooling.^{145,146}

Xenobiotic Metabolism in Therapeutic Hypothermia. Hypothermia is induced for its neuroprotective effects but requires attention to alterations in pharmacokinetics and pharmacodynamics of xenobiotics administered during hypothermia. Physiological changes during induced hypothermia are similar to those of unintentional hypothermia and include slowed enzymatic reactions, vasoconstriction, decreased cardiac output, and hemoconcentration. Studies support a decrease in the V_d of pancuronium, midazolam, morphine, and gentamicin.⁶⁵ Clearance of xenobiotics is affected by organ perfusion, enzyme activity, and xenobiotic characteristics such as the degree of protein binding and the pK_a . Hepatic and renal clearance is affected by regional blood flow, which is decreased during hypothermia. In general, the decrease in the V_d and the decrease in clearance result in increased serum xenobiotic concentrations.²³ Experimental studies in animals demonstrate a 25% increase in fentanyl concentrations at a core temperature of 32°C.⁹³ Concurrent supportive modalities during hypothermia such as cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) further alter the kinetics of xenobiotics during hypothermia.²⁹⁰ In neonates, asphyxia treated with induced hypothermia presents the additional complication of rapidly changing neonatal physiology and the effects of supportive measures such as ECMO.⁶⁵

Clinical Findings

The clinical effects of hypothermia are related to the membrane depressant effects of cold, which result in ionic and electrical conduction disturbances in the brain, heart, peripheral nerves, and other major organs (Table 30–4).¹³¹ Cold tissues are protected by decreases in tissue oxygen requirements. As body temperature decreases, metabolic activity declines at a rate of approximately 7% per 1.8°F (1°C).²⁹⁵ This effect provides significant protection to vital organs despite the potentially deleterious effects of membrane suppression.

TABLE 30–4. Physiologic and Clinical Manifestations of Hypothermia

Cardiovascular

Normal, decreased, or increased cardiac output

Normal heart rate or tachycardia, then bradycardia as hypothermia increases

Vasoconstriction and central shunting of blood

Electrocardiogram

Prolongation of intervals

Atrial fibrillation

Increased ventricular irritability

J-point elevation “Osborn waves”

Central nervous system

Mild: 90°–95°F (32°–35°C)

Normal mental status or slightly slowed

Moderate: 80°–90°F (27°–32°C)

Lethargic but verbally responsive

Severe: 68°–80°F (20°–27°C)

Unlikely to respond verbally or purposefully to noxious stimuli

Profound: <68°F (<20°C)

Unresponsive; may “appear dead”

Gastrointestinal tract

Decreased motility

Depressed hepatic metabolism

Hematologic

Hemoconcentration

Left shift of oxyhemoglobin dissociation curve

Kidneys

Cold-induced diuresis

Antidiuretic hormone antagonism

Lungs

Hyperventilation to hypoventilation with increasing hypothermia

Bronchorrhea

Metabolic

Metabolic acidosis

Increased glycogenolysis

Increased serum free fatty acids

Normal thyroid and adrenal function

Effects on the CNS are temperature dependent and predictable. Mild hypothermia (90–95°F; 32.2–35°C) usually results in relatively benign clinical manifestations. Ataxia, clumsiness, slowed response to stimuli, and dysarthria are common.⁹⁰ As cooling continues, the mental status slowly deteriorates. In moderate hypothermia (80–90°F; 27–32.2°C), the patient is usually lethargic but still likely to respond verbally. In severe hypothermia (68–80°F; 20–26.6°C), the patient is unlikely to respond verbally but will react purposefully to noxious stimuli.^{90,122} In profound hypothermia (<68°F; <20°C), the patient is unresponsive to stimuli. The pupils may be fixed and dilated and the patient may appear dead.¹²² However, standard criteria for brain death do not apply to hypothermic patients. The hypothermia itself protects against cerebral hypoxic damage.¹³¹ Temperature drop inhibits the release of the excitatory neurotransmitter glutamate and attenuates the release of dopamine in animal models of brain ischemia, suggesting a protective effect of hypothermia in brain injury.³⁹ Cerebrospinal fluid (CSF) glutamate concentrations were lower in patients showing benefit from mild induced hypothermia after brain injury compared with brain-injured patients kept normothermic.¹⁸⁵

Patients have survived with body temperatures as low as 48.2°F (9°C).⁹⁴ Vigorous resuscitation is required for these patients. This approach may lead to hours of cardiopulmonary resuscitation (CPR) of hypothermic patients with ventricular fibrillation, ventricular tachycardia, or asystole but may be ultimately successful in resuscitating patients initially presumed to be dead.²⁶²

For field rescue work, the Swiss distinguish between five stages of hypothermia and provide guidelines for rescue in dangerous environmental conditions. These stages are based on the degree of consciousness, the presence or absence of shivering, cardiac activity, and core temperature.^{74,35} The adage that a patient cannot be considered dead until the patient is warm and dead is further refined by the Swiss guidelines for field rescue attempts under avalanche conditions.

The cardiac and hemodynamic effects of cold correlate closely with body temperature. As cooling begins, there is a transient increase in cardiac output. Tachycardia develops secondary to shivering and sympathetic stimulation. At about 81°F (27.2°C), shivering ceases. Bradycardia develops with maintenance of a normal cardiac stroke volume.³⁷ This bradycardia is responsible for the decreased myocardial oxygen demand, which may be protective in the setting of hypothermia.³⁷ In profound hypothermia, bradycardia may progress to asystole and death.

Unlike cerebral circulation, in which autoregulation is preserved during cooling, coronary autoregulation is disturbed during hypothermia, and myocardial injury may ensue.³⁷ Attempts to maximize myocardial oxygenation through administration of oxygen and volume replacement to increase diastolic filling pressures are appropriate.

The initial response to cold is hyperventilation; however, as temperature continues to decrease, hypoventilation develops, which may progress to apnea and death. In animal models, this has been attributed to cold-induced failure of phrenic nerve conduction.¹⁵⁴

The Electrocardiogram

The most common electrocardiographic (ECG) abnormality in hypothermia is generalized, progressive depression of myocardial conduction. PR, QRS, and QT intervals are all prolonged, and increasingly profound hypothermia may lead to gradual progression to asystole.^{73,277} Ventricular fibrillation occurs in an irritable myocardium most commonly at temperatures less than 86°F (30°C), resulting in a high O₂ consumption dysrhythmia. Atrial fibrillation is the most common dysrhythmia occurring in the presence of hypothermia.^{91,219} Shivering may not be clinically evident, but the characteristic fine muscular tremor frequently produces a mechanical artifact in the baseline of the ECG.⁷⁸ A deflection occurring at the junction of the QRS and ST segment is invariably present in patients with temperatures <86°F (<30°C) (Fig. 30–3). First described in a single patient in 1938, the J-point deflection is commonly known as the Osborn wave.^{79,222,273} The J-point deflection, thought to be a “current of injury” associated with CO₂ retention under hypothermic conditions, was believed to be a poor prognostic sign.²²² Subsequent study does not support any prognostic significance because the J-point deflection is invariably found in hypothermic patients when multiple ECG leads are obtained.^{78,79,275,282} The size of the J-point deflection increases as body temperature decreases.^{219,282} Atrial dysrhythmias that occur in the absence of underlying heart disease invariably disappear solely with rewarming.

FIGURE 30–3. Relation of rewarming rate to underlying illness. (Reprinted with permission from Academic Emergency Medicine.⁶⁸)

Management

After blood specimens are drawn, the hypothermic patient in whom hypoglycemia is present should be given 0.5 to 1.0 g of dextrose/kg of body weight as D₅₀W (50% dextrose in water in adults or D₂₀W or D₁₀W as appropriate for children) and 100 mg of IV thiamine. If hypoglycemia is the cause of the hypothermia, the response to dextrose may be dramatic, heralded by the onset of shivering and rapid return to normal body temperature. Wernicke encephalopathy is uncommon but may be associated with mild hypothermia; thermoregulation and normal ocular motion may return after the initiation of thiamine therapy.¹⁶¹

Hypothermia shifts the oxygen dissociation curve to the left (Chap. 29), resulting in decreased oxygen unloading to tissues; therefore, oxygen administration may be of benefit.⁶⁷ If clinically indicated, endotracheal intubation should be performed for airway protection or inadequate ventilation or oxygenation.^{62,168,198} However, there are case reports of ventricular fibrillation occurring during endotracheal intubation.^{15,100,122,223,291} Every effort should be made to limit patient activity and stimulation during the acute rewarming period because activity may increase myocardial oxygen demand or alter myocardial temperature gradients, increasing the risk of iatrogenic ventricular fibrillation. Although pulmonary artery catheters and central venous lines have been inserted without complications, they should be avoided unless absolutely essential so as not to precipitate ventricular dysrhythmias.^{120,169,274} If a central venous catheter is considered necessary, it should not be allowed to touch the endocardium.²⁷⁶ Patients who develop ventricular fibrillation or asystole are difficult to manage because of the many supportive therapies required at once and the often lengthy resuscitation efforts. In these instances, CPR should be initiated and the patient intubated and ventilated to maintain a pH of 7.40, uncorrected for temperature. Active internal rewarming (see later discussion) should be instituted in the patient in cardiac arrest because standard therapy for ventricular fibrillation or asystole may be unsuccessful until rewarming is achieved. There is a risk of toxicity if multiple doses of drugs are administered in the hypothermic patient in whom drug metabolism is altered and circulation is arrested. However, based on current research discussed later, it is reasonable to incorporate pharmacotherapy into the management of hypothermic cardiac arrest. A vasopressor, either epinephrine or vasopressin, may be given to increase the coronary perfusion pressure.²⁹² Amiodarone or lidocaine may then be administered if ventricular fibrillation is present. Defibrillation may not be successful until the temperature exceeds 86°F (30°C); however, defibrillation can be successfully accomplished in animals and patients with temperatures of less than 86°F (30°C).^{5,15,63,292} A reasonable approach is that if defibrillation is unsuccessful, defibrillation should not be attempted again until the patient has been warmed several degrees centigrade. Individuals presenting with cardiac arrest and hypothermia may appear dead yet respond to rewarming and resuscitative efforts. Pneumatically powered devices capable of mechanical chest compression and cardiopulmonary bypass are used successfully during prolonged hypothermic cardiopulmonary arrests.^{15,55,172,263,274}

Arterial Blood Gas Physiochemistry in Hypothermia

Assessment of the adequacy of ventilation and oxygenation in the hypothermic patient often poses a dilemma to clinicians because the chemical effects of cold on arterial pH and blood gases lead to confusion in the interpretation of arterial blood gas values. Cold inhibits the dissociation of water molecules, causing pH to increase as cooling occurs. In vitro, the pH change of blood as it is cooled increases parallel to the pH change of neutral water. The partial pressures of CO₂ and O₂ decrease as cooling occurs even as the blood content of those gases remains unchanged. Blood in a syringe taken from a

patient whose body temperature is 98.6°F (37°C) yields a pH of 7.40 and a PCO₂ of 40 mm Hg in the blood gas machine at 98.6°F (37°C) but yields a pH of 7.72 and a PCO₂ of 14 mm Hg if the blood is cooled to 61°F (16°C) and the values are measured at that temperature. Specially calibrated laboratory equipment, not routinely available, is required to measure blood gas values directly at other than normal body temperature. A patient whose body temperature is 61°F (16°C) and whose actual in vivo blood gas values are a pH of 7.72 and PCO₂ of 14 mm Hg will have a pH of 7.40 and PCO₂ of 40 mm Hg when the blood is warmed to 98.6°F (37°C) and measured in the standard laboratory blood gas machine. Because the machine measures pH and blood gas pressures only in blood warmed to 98.6°F (37°C) (the uncorrected values), the actual in vivo values in hypothermic patients can be approximated using mathematically derived corrected values. Because the pH of neutrality has also increased, it is unclear what clinical meanings these corrected values have. The uncorrected values indicate what the pH and PCO₂ would be if the patient were normothermic. At first glance, the clinician might be content to learn that a hypothermic patient at 61°F (16°C) has a corrected pH of 7.47 and PCO₂ of 40 mm Hg. However, the uncorrected values in the blood gas machine at 98.6°F (37°C) of pH of 7.18 and PCO₂ of 111 mm Hg indicate that the patient has a significant respiratory acidosis. Attempts to maintain a corrected pH of 7.40 may lead to hypoventilation and risk alveolar collapse and impairment of oxygenation. The preponderance of evidence in the anesthesia and cardiovascular surgery literature suggests that maintenance of ventilation is associated with a decreased incidence of myocardial injury and a decreased incidence of ventricular fibrillation.⁶⁷ Thus, the pH and PCO₂ blood gas values should be left uncorrected after the blood sample is warmed in the blood gas machine and interpreted in the same way as in a normothermic patient.⁶⁷

Hypotension

When hypotension occurs in a patient with hypothermia, it may be a result of the presence of bradycardia and volume depletion. However, hypotension may be a predictor of infection, particularly when associated with a slow rewarming rate. Fluid depletion in hypothermia occurs as a result of a variety of mechanisms, including central shunting of blood by vasoconstriction and cold-induced diuresis. Cold diuresis occurs when increases in central blood volume result in inhibition of the release of antidiuretic hormone. Impairment of renal enzyme activity and decreased renal tubular reabsorption contribute to the large quantities of dilute urine known as cold diuresis.^{116,121,169,295} 0.9% NaCl should be given to expand intravascular volume. Urine output is an important indicator of organ perfusion and the adequacy of intravascular volume in hypothermic patients, although the initial cold diuresis may lead to underestimation of fluid needs.²⁹⁵

Pharmacologic Interventions

The best means to effect resuscitation of a hypothermic victim in ventricular fibrillation is controversial. The most recent recommendations of the American Heart Association (AHA) for the treatment of cardiac arrest when the core body temperature is below 86°F (<30°C) states that the administration of a vasopressor or antidysrhythmic according to standard Advanced Cardiac Life Support algorithm concurrent with rewarming may be reasonable.²⁷⁹ A metaanalysis of animal studies of antidysrhythmic and vasopressor therapy for ventricular fibrillation in the setting of hypothermia found that there was significant improvement in the return of spontaneous circulation (ROSC) in animals that received epinephrine or vasopressin.²⁹² In this report, the authors could not identify a benefit to the use of amiodarone administered without a vasopressor. They postulated that this is most likely due to the improvement in coronary perfusion pressure caused by vasopressors during cardiac arrest.²⁹²

Epinephrine and Vasopressin. The administration of vasopressin to pigs in hypothermic cardiac arrest increased coronary perfusion pressure and improved defibrillation success.²⁵² In a pig model, when warmed thoracic lavage was used, vasopressin increased coronary perfusion pressure and increased the 1-hour survival.²⁵¹ In this study, the administration of 0.9% NaCl resulted in zero episodes of successful defibrillation, but all eight vasopressin-treated pigs had restoration of spontaneous circulation after electrical defibrillation and improved short-term survival. The whole-body temperature was not increased, but the authors postulated that myocardial warming may have occurred.²⁵¹ In another study in which epinephrine was given to one group of pigs and vasopressin to another, increased coronary perfusion pressure and ROSC resulted in both groups.^{165,166} In contrast, body temperature significantly increased during CPR with thoracic lavage, and epinephrine increased coronary perfusion pressure, but no improvement in ROSC occurred.¹⁶⁴ The length of time of cardiac arrest, the doses of drug, and the efforts to rewarm differed in these studies. A 19 year-old patient who had a prolonged hypothermic cardiopulmonary arrest showed no improvement after 2 mg of epinephrine but had immediate restoration of spontaneous circulation after the administration of vasopressin.²⁶⁹ Interactions with epinephrine, vasopressin, and ischemia during CPR are complex and incompletely understood.¹⁶⁷

Amiodarone. Amiodarone is recommended in the current AHA algorithm for ventricular fibrillation in normothermia. In one study comparing the use of amiodarone, bretylium, and placebo in a hypothermic dog model, amiodarone showed no statistical improvement in causing ROSC. There was no significant difference among the groups; only one of 10

amiodarone-treated dogs demonstrated ROSC versus three of 10 in the placebo group and four of 10 in the bretylium-treated dogs.²⁶⁷ However, in a study in which hypothermic dogs in ventricular fibrillation were treated with epinephrine before administration of 10 mg/kg of amiodarone, there was a significantly higher rate of ROSC.²⁹²

Dopamine. Dopamine increases cardiac output, mean arterial pressure, heart rate, and stroke volume in dogs cooled to 77°F (25°C) and stabilizes pulmonary arterial wedge pressure.²⁰⁸ In a canine hypothermia model, dopamine infusions provided some protection from ventricular fibrillation. Dopamine lowered the temperature at which ventricular fibrillation occurred and reduced the incidence of ventricular fibrillation, as did infusion of norepinephrine.⁹ The added benefit of dopamine in hypothermia may be a result of its renal and splanchnic vasodilating properties, increasing renal perfusion and supporting urine output.¹⁰⁴ Dopamine increases myocardial oxygen demand and decreases peripheral perfusion, potentially detrimental effects in hypothermic patients.⁹

Rewarming

Three types of rewarming modalities are used in the management of hypothermic patients.^{58,79} Passive external rewarming involves covering the patient with blankets and protecting the patient from further heat loss. Passive external rewarming uses the patient's own endogenous heat production for rewarming and is most successful in healthy patients with mild to moderate hypothermia whose capacity for endogenous heat production is intact.¹²¹ Passive external rewarming is reported to be successful in hypothermic patients with temperatures as low as 69°F (20.6°C).^{272,282,289} Advocates of passive external rewarming argue that it allows vasoconstriction to persist and decreases the afterdrop and shock from vasodilation associated with active skin rewarming.^{121,198,272}

Active external rewarming involves the external application of heat to the patient. There is disagreement about the possible detrimental effects of active external rewarming. For example, skin warming may lead to a physiologically detrimental suppression of shivering.¹²¹ Acute vasodilation of peripheral vessels could cause hypotension and an increased peripheral demand on the persistently cold myocardium. The return of cold blood from the extremities to the heart is suggested to exacerbate intramyocardial temperature gradients, which could cause ventricular irritability during hypothermia.¹⁸⁶ However, in pigs, blood returning to the heart was found to be warm before warming of central organs occurred.¹⁰⁵

Afterdrop is the continuing decrease in temperature after rewarming begins. There is no evidence that it occurs in humans.²⁶⁸ In one study of 33 patients with core temperature below 82.4°F (<28°C), no patient experienced afterdrop during peripheral rewarming.²³⁴ There is no evidence of pooling of blood in the periphery nor of increased flow during surface rewarming.^{179,247} Flow studies in the hand, arm, calf, and foot demonstrate that afterdrop has already occurred and is completed before any increase in blood flow occurs in the limbs.^{179,286} Initial experiments demonstrating afterdrop were done in inanimate objects and reflected continued cooling of central structures before heat from external sources reached the core.^{105,179,286}

Mortality rates for active external rewarming are frequently reported to be higher than for passive external rewarming,²²⁹ but case selection is not controlled in these series. Sicker patients with stable cardiac rhythms who fail to rewarm passively and are then actively rewarmed have a higher mortality rate directly correlated with their underlying disease rather than by the method of therapy.⁶⁸ Selection of either passive or active external rewarming in treatment of mild to moderate hypothermic patients with perfusing cardiac rhythms does not appear to influence the prognosis as much as the presence or absence of underlying disease.^{68,134,198,288} In our experience, active external rewarming has not resulted in death except in patients with severe underlying disease.⁶⁸

Active internal rewarming involves attempts to increase central core temperature directly by warming the heart before the extremities or periphery. Minimally invasive modalities of active internal rewarming include the administration of heated, humidified oxygen delivered by face mask or endotracheal tube¹²³ and gastric lavage with warmed fluids. More invasive modalities, procedures that are fundamental to the rewarming controversy, include peritoneal lavage with warmed dialysate^{140,213} and the rerouting of blood through external blood rewarming equipment via cardiopulmonary or femoral–femoral bypass and hemodialysis.^{42,128,204} Heparin-coated bypass systems are available that avoid systemic anticoagulation, thus decreasing the risk of bleeding complications. It is suggested that extracorporeal venovenous rewarming and continuous arteriovenous rewarming show improved rewarming rates compared with standard techniques such as saline lavage of the bladder, stomach, or peritoneal cavity.⁹⁸ Extracorporeal methods of active internal rewarming should be reserved for severely hypothermic patients (<80°F or <27°C) or those with unstable cardiac rhythms (ventricular fibrillation, ventricular tachycardia, or asystole) attributed to hypothermia.^{5,66,117} In patients with stable rhythms, studies are essential to resolve the debate over the merits of passive or active external rewarming versus active internal rewarming. Transcutaneous pacing was successful in improving hemodynamic parameters and speeding rewarming in an animal model.⁷⁵

Many patients with temperatures below 86°F (30°C) have been successfully treated with passive external rewarming

with, at most, the addition of warm, humidified oxygen.^{68,259,289} Patient temperature correlates poorly with outcome.^{5,63,168,274,277} Treatment recommendations should not be based solely on temperature. Stability of the vital signs and cardiac rhythm and the underlying cause of hypothermia are much more critical considerations in management.

Hyperkalemia is not described as a consequence of rewarming.⁶² In all of the evidence collected with regard to hyperkalemia, this abnormality was present as a consequence of the hypothermia and not the rewarming.^{122,183,248}

Prognosis in Hypothermia

Except in cases of profound hypothermia,¹²² the prognosis is most closely correlated with the presence or absence of underlying disease.^{134,198,216,288,289} In patients with hypothermia alone, in the absence of underlying disease, the mortality rate is 0% to 10%. In the presence of a severe underlying disease such as sepsis, the mortality rate is much greater.⁶⁸ Morbidity results from associated frostbite and trauma.

Prolonged cardiopulmonary arrest and absolute temperature are not predictive of poor outcome.^{5,63,168,274,277} In severely hypothermic patients, profound hyperkalemia ($K^+ > 10$ mEq/L) is associated with unsuccessful resuscitation.^{122,183,248}

Frostbite. Hypothermia may be accompanied by frostbite when patients are exposed to environmental temperatures that are lower than 20°F (6.7°C).¹⁹⁹ Frostbite should be managed by rapid rewarming of the frozen part of the affected person. The extremity involved may be placed in a large, soft basin of warm water (100–108°F; 38–43°C) for 30 minutes. The water temperature must be frequently adjusted because the frozen extremity will cool the water in the basin. Parenteral analgesics may be necessary because the rewarming process is often painful. Frostbitten areas should never be rubbed because the tissue is particularly sensitive to trauma.

HYPERTHERMIA

Definition of Heatstroke

Heatstroke is defined by a rectal temperature greater than 106°F (41.1°C) in the setting of a neurologic disturbance manifested by mental status changes, including confusion, delirium, stupor, coma, or convulsions.¹⁵⁶ Temperature criteria cannot be absolute because information regarding the patient's temperature is rarely available at the time of onset of heatstroke. In some instances, the temperature may not be measured for several hours, during which time cooling may have been instituted or occurred spontaneously.^{150,151} When appropriate environmental conditions prevail, the diagnosis of heatstroke should be made liberally. Although the absence of sweating was once thought to be an essential component of the definition of heatstroke,^{53,214} many patients with heatstroke maintain the ability to sweat.^{61,184,256,283}

Epidemiology of Heatstroke

Hundreds of people die annually of heatstroke in the United States, 80% of whom are older than age 50 years. When counting heat-related fatalities, the number is underestimated if only death certificates are included in which hyperthermia is listed as the underlying cause of death. Including hyperthermia as a contributing factor to death increased the total number of heat-related deaths by 54% from 1993 to 2003.⁴⁴ Several studies show mortality rates from heatstroke to be 5.6% to 80%. Thousands of other victims survive with significant heat-related morbidity.^{8,260} The high morbidity and mortality of heatstroke markedly contrast with those of profound hypothermia, in which the prognosis is related not to the temperature itself but to the underlying etiology. The overall prognosis in heatstroke depends primarily on how long the temperature has been elevated before cooling, the maximum temperature reached, and the affected individual's premorbid health.

Heat-related deaths are preventable, and the public health preparedness of cities, health care workers, and the community is essential.^{16,45} The mortality rate during heat waves are increased in urban areas where a heat wave has not occurred for several years.^{52,77,141,250} The mortality rate is decreased when public health interventions improve preparedness. The city of Milwaukee experienced a heat wave in 1995 that resulted in numerous public health and preparedness responses. These efforts may have resulted in a diminution by 49% of the number of heat-related deaths and emergency medical service runs in the heat wave of 1999.²⁸⁷ After the Chicago heat wave of 1995, public policies targeting the elderly adults of Chicago may have contributed to a change in the demographics of those who succumbed during a subsequent heat wave in Chicago in 1999. The dead in 1999 were younger; more than 50% of those who died were younger than age 65 years. More than half of the dead were seen or spoken to on either the day of or the day before their death. Psychiatric illness was almost twice as common in the younger victims compared with those older than 65 years of age.²⁰⁷

Heat waves are meteorological events characterized by air temperatures that are 90°F or above ($\geq 32.2^\circ\text{C}$) for 3 or more consecutive days.⁴⁴ During the summer of 2003, Europe experienced record high temperatures for many consecutive days. The prolonged heat caused extreme increases in mortality rates across Europe. In France, there were 14,800 excess deaths caused by heat. This is equivalent to a total mortality rate increase of 60% between August 1 and August 20,

2003.^{170,280} In a follow-up report of 83 of these victims, the mortality rate at 2 years was 71%.¹⁰ Survivors had dramatic decreases in their ability to function.¹⁰ From June to August 2003, Italy reported 1094 excess deaths, a 23% increase compared with the average annual number of deaths from 1995 to 2002.⁴⁵ An increased mortality rate was associated with risk factors previously reported, including old age, limited access to care, poor living conditions, and social isolation.²⁵³

Socially isolated individuals, people with preexisting illnesses, physically compromised individuals, and frail elderly adults are at greatest risk of death during heat waves. Confinement to bed was the strongest predictor of death in the Chicago heat wave of 1995, and living alone doubled the risk of death. There were fewer deaths among people with working air conditioners or who had access to an air-conditioned environment.^{235,253} Although fans may seem to improve comfort, they do not prevent heat-related illness and may contribute to heat stress when temperatures and humidity exceed approximately 100°F (37.8°C).^{148,152,153,207,253,294} Prisoners incarcerated in hot conditions die of heatstroke.³⁸ In times of heat waves, preventive public health programs should encourage visiting nurses, housekeepers, and community service programs to increase the awareness of the danger of heat and identify individuals most at risk.²⁵³ A decreased risk of death was found among people with contacts from these agencies during the Chicago heat wave.²⁵³ The media must alert the public and provide information on avoiding heat illness, as well as encourage individuals to help others to stay cool by ensuring access to cooling measures.

The number of deaths from exposure-related illness has increased threefold in foreign transients attempting to enter the United States from Mexico. Because urban areas are more tightly patrolled, individuals attempting to cross into the United States illegally have turned to the harsh deserts and mountain ranges of the southwestern United States, increasing prolonged exposure and resulting in death from heat, cold, and dehydration. Although many more bodies remain undiscovered, 99 individuals' deaths were attributed to environmental causes in the year 2000, many of them caused by heat.⁸²

From 1995 to 2002, 233 children died from heatstroke when left unattended in cars, 75% of whom were either forgotten or left by caretakers who did not expect the temperature to rise dangerously within the automobile. In 25% of the incidents, children were trapped inadvertently while playing. Most of these deaths occurred during the summer months.¹¹¹

Infants may suffer heatstroke under environmental conditions that would not be expected to place a child in danger. Well-meaning parents sometimes overinsulate children with clothing and blankets, inhibiting their cutaneous heat loss and placing them at risk.^{14,137,138}

During 2002, the US military reported 1816 heat-related injuries of active duty soldiers.⁶ During Operation Iraqi Freedom, six soldiers died from heat-related causes. There were 30 other cases of heatstroke and many other heat-related casualties. During the period from 1997 to 2002, 8084 soldiers were treated as outpatients for heat injuries.⁶ The US military actively promotes heat illness prevention and exhorts its personnel to not repeat history. In comparison, in 1917, 425 British soldiers on active duty in the area on the Persian Gulf (formerly known as Mesopotamia; presently known as Iraq) died of heatstroke during 1 month, and 524 died in 1 year.²⁹¹

There were 114 heatstroke deaths among football players from 1960 to 2007. From 1995 to 2007, 33 football players died of heatstroke—25 high school, five college, two professional, and one sandlot.²⁷⁸

High ambient temperature is associated with an increase in mortality from cocaine overdose. The mean daily number of deaths from cocaine overdose was 33% higher when the ambient temperature exceeded 88°F (31°C).¹⁸⁶

Thermoregulation and Heat Stress

The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. Increased body core temperature results in active dilation of cutaneous vessels, and skin blood flow increases.^{126,238} Because increased skin blood flow is attained primarily by an increase in heart rate and stroke volume, the capacity to increase cardiac output is critical to cooling. Compensatory shifting of blood flow from the splanchnic and renal vessels to the skin further increases skin blood flow.^{133,238} The combination of vasodilation, increased skin blood flow, and increased sweating results in heat loss through convection and evaporation. Dehydration after profuse sweating increases plasma osmolality. Heat-sensitive neurons in the preoptic anterior hypothalamus are inhibited by locally increased osmolality and by input from distal hepatportal osmoreceptors. The inhibition of heat sensitive neurons results in decreased heat dissipation response.^{51,217}

Types of Heatstroke

Heatstroke is commonly divided into two types, exertional and nonexertional. Nonexertional, or classic, heatstroke describes heatstroke occurring in the absence of extreme exertion. Nonexertional heatstroke is most commonly described during heat waves, and the victims are predominantly those persons least able to tolerate heat: infants,¹⁴ older adults,⁵⁷ individuals with psychiatric disorders, and chronically ill individuals.

Exertional heatstroke occurs as a result of increased motor activity. It may occur in young, healthy individuals who are

exercising or in individuals whose increased motor activity results from other causes, such as seizures or agitation. Often a period of significant heat stress in exercising individuals precedes the development of heatstroke. Military recruits who develop heatstroke may sometimes present to the camp infirmary with vague complaints before collapse.²⁵⁶ Published studies of heatstroke in miners, athletes, and military recruits describe several precipitating factors in heatstroke, including fatigue associated with a recent deficit in sleep, poor physical conditioning, a recent febrile illness, recent heat-related symptoms such as thirst or weakness, relative volume depletion, failure to allow for acclimatization, and obesity. Symptoms of nausea, weakness, headache, diarrhea, or irritability often precede the development of heatstroke. Although rapid onset of symptoms and acute loss of consciousness are frequently reported in exertional heatstroke, the preceding period of heat stress and insidious symptoms may go unrecognized. Although exertional heatstroke is more likely to occur during intense exertion in a hot, humid environment, it may also occur with moderately intense exercise early in the morning, when environmental conditions do not usually represent a thermoregulatory stress.¹²

Differential Diagnosis of Hyperthermia

In addition to exposure and exertion, conditions that predispose to severe hyperthermia include primary hypothalamic lesions, intracranial hemorrhage, agitation, alcohol and sedative-hypnotic withdrawal, seizures, and the use of therapeutic and illicit xenobiotics (Table 30–5).^{102,107–109,165,187,270} The differential diagnosis may include serotonin toxicity, malignant hyperthermia, or the neuroleptic malignant syndrome, conditions causing high temperature, altered mental status, and increased muscle tone. These conditions are much less common than classical or exertional heatstroke resulting from impaired thermoregulation caused by the effects of therapeutic xenobiotics.

TABLE 30–5. Differential Diagnosis of Hyperthermia

I. Increased heat production

- Increased muscle activity
 - Agitation
 - Catatonia
 - Ethanol withdrawal
 - Exercise
 - Infectious diseases
 - Malignant hyperthermia
 - Monoamine oxidase inhibitor drug interactions
 - Neuroleptic malignant syndrome
 - Parkinson disease
 - Sedative-hypnotic withdrawal
 - Seizures
 - Serotonin toxicity
 - Xenobiotics
- Increased metabolic rate
 - Hyperthyroidism
 - Pheochromocytoma
 - Sympathomimetics

II. Impaired heat loss

- Environmental
 - Heat
 - Humidity
 - Lack of acclimatization
- Social disadvantage
 - Confinement to bed
 - Isolation
 - Lack of air conditioning
 - Poverty

- Medical illness
 - Cardiac insufficiency
 - CNS dysfunction
 - Diabetes
 - Hypertension
 - Pulmonary
- Dehydration
- Fatigue
- Limited behavioral response
 - Extremes of age
 - Intellectual disability
 - Psychiatric impairment
 - Xenobiotics

Serotonin Toxicity. Serotonin toxicity, results from excess stimulation of the serotonin receptors, primarily the 5-HT_{1A} subtype.²⁶⁶ Drug interactions are most commonly the cause. Monoamine oxidase inhibitors used in conjunction with tricyclic antidepressants,¹⁶ selective serotonin reuptake inhibitors,⁸⁵ L-tryptophan,^{85,271} meperidine,¹¹⁸ dextromethorphan,²³³ and amphetamines,¹⁶⁵ are reported to lead to serotonergic hyperstimulation and severe symptoms.^{103,266} The clinical condition resulting from excess serotonin includes alterations in consciousness, restlessness, increased muscle tone, tremor, GI disturbances, and hyperthermia. Treatment focuses on control of hyperthermia by using aggressive cooling; muscle relaxation primarily by using benzodiazepines; or, in severe cases, endotracheal intubation and paralysis (Chap. 75).

Malignant Hyperthermia. Malignant hyperthermia is a very rare disorder, that is associated with a congenital disturbance of calcium regulation in striated muscle. Malignant hyperthermia was first reported in 1960. Ten deaths occurred in a single family after general anesthesia.⁷² Exposure to anesthetics; depolarizing muscle relaxants; or, rarely, severe exertion precipitates uncontrolled calcium efflux from the sarcoplasmic reticulum, leading to severe muscle rigidity and hyperthermia.^{110,139} The clinical setting of severe muscle rigidity and hyperthermia after general anesthesia usually is adequate to define the syndrome (Chap. 69). In other words, malignant hyperthermia is a pharmacogenetic disorder of the ryanodine receptor causing increased sensitivity to certain xenobiotics.^{119,246}

Neuroleptic Malignant Syndrome. Neuroleptic malignant syndrome, a severe extrapyramidal syndrome associated with muscle rigidity, autonomic dysfunction, and altered mental status, was first described in 1968.⁶⁹ This disorder develops during the administration of antipsychotics or the withdrawal of dopaminergic xenobiotics. Increased muscle tone because of dopaminergic blockade of the striatum as well as central altered hypothalamic thermoregulation leads to hyperthermia.¹²⁴ Temperature elevation and alteration of mental status occur after the onset of “lead pipe” muscle rigidity.^{21,114} Laboratory findings are not specific and include a marked elevation of creatine phosphokinase (CPK) in some patients and leukocytosis with a left shift. Neuroleptic malignant syndrome must be distinguished from the much more common cases of heatstroke in psychiatric patients that are caused by heat intolerance resulting from the anticholinergic effects of antipsychotics or antihistamines prescribed to control extrapyramidal symptoms (Chap. 70).^{243,297}

Inflammatory Mediators in Heatstroke

The response to heat stress is a coordinated interplay between the mediators of inflammation, including endothelial cells, leukocytes, inflammatory cytokines, and endotoxins. These are important mediators of the systemic immune response. However, in heatstroke, they are responsible for systemic inflammation and activation of the coagulation cascade, similar to the systemic inflammatory response syndrome (SIRS). Many proinflammatory cytokines are identified in heatstroke, including tumor necrosis factor (TNF); interleukins-2, -6, -8, -10, and -12; interferon- α and - β ; and granulocyte colony-stimulating factors.²⁸ In one study of 18 heatstroke patients, circulating cytokine concentrations correlated with clinical indices of heatstroke severity.¹³⁵ Cooling delays the release of interleukin-1 β , interleukin-6, and TNF in vitro.¹⁵⁵ Studies in hyperthermic animals focus on the modulation of the mediators of inflammation as possible future adjuncts to cooling. In another study, recombinant human activated protein C provided cytoprotection by decreasing release of inflammatory cytokines but did not improve survival.²⁹ Whole-body cooling restored appropriate concentrations of cardiac tissue protein associated with loss of structural integrity of the cardiac myocytes and reversed cardiac dysfunction.⁴⁸

Heat stress causes increased gene transcription of heat shock proteins, which render the organism more resistant to heat injury, protecting cells from injury and increasing cell survival. Heat shock protein 72 is protective against injury and from heat stress, and the extent of protection correlates with the concentration of heat shock protein.¹⁸⁰

During exercise, splanchnic hypoperfusion increases the translocation of bacteria from the gut into the bloodstream,

establishing the cascade of inflammation and injury that perpetuates tissue injury after normothermia is established.⁸³

Pathophysiologic Characteristics of Heatstroke

In heatstroke, hypotension and tachycardia are caused by a number of factors. The patient with heatstroke may have a reduced plasma volume secondary to salt and water depletion. Peripheral pooling of blood is associated with an increase in cutaneous blood flow from 0.5 L/min to 7 to 8 L/min.^{133,238} In addition, patients may manifest primary myocardial insufficiency.¹⁵⁷ Clinically, patients exhibit either a hypo- or hyperdynamic circulatory response. The observed circulatory response to heat stress is a function of the patient's cardiac reserve, volume status, and degree of myocardial heat injury. The hyperdynamic condition is characterized by increased cardiac index and decreased systemic vascular resistance.²¹⁵ These hemodynamic characteristics occur in patients who are able to maintain a significantly increased cardiac output in response to the circulatory demand of heat stress.

Volume-depleted patients and those patients with primary myocardial insufficiency may exhibit a hypodynamic response. These patients have a decreased cardiac index and increased systemic vascular resistance.^{215,265} Whether pulmonary vascular resistance is affected is unclear. High central venous pressures (CVPs) have been found in some patients, with evidence of right heart failure and right heart dilation on autopsy.¹⁸⁴ These findings have led to the suggestion that pulmonary vascular resistance may be elevated.²¹⁵ In 22 of 34 patients with heatstroke, CVPs were greater than 3 cm H₂O. Twelve patients had a CVP of 0 cm H₂O, and 10 had a CVP that exceeded 10 cm H₂O. These authors cautioned against injudicious infusion of large quantities of IV fluids that can result in complications of congestive heart failure and fluid overload. In the study, only three patients required more than 2 L of 0.9% sodium chloride solution during cooling. Crystalloid infusion ranged from 500 to 2500 mL, and none of the patients developed problems associated with fluid overload.²⁵⁴

A study of compromised elderly patients with heatstroke using pulmonary artery catheters showed that pulmonary vascular resistance was low or normal. Pulmonary capillary wedge pressures were not elevated.²⁶⁴ A study of 13 cases of heatstroke in pilgrims to Mecca, Saudi Arabia, monitored with pulmonary artery catheters demonstrated a good correlation of CVP with pulmonary capillary wedge pressures.² Serial ECGs in 51 of these pilgrims with heatstroke showed normal sinus rhythm in 25%, sinus tachycardia in 52%, atrial fibrillation in 16%, and sinus bradycardia in 6%. ST segment depression and other ST-T wave changes were reported. The QT interval showed no abnormality.³ ST changes suggestive of acute coronary syndrome may occur and normal coronary arteries are noted on coronary catheterization.²⁰² In some patients, echocardiography showed pericardial effusions and regional wall motion abnormalities, asymmetric septal hypertrophy, right ventricular dilation, and left ventricular dilation with impaired function.³

Autopsy studies of the heart demonstrate right heart dilation, pericardial effusions, interstitial edema, degeneration and necrosis of myocardial fibers, and subendocardial hemorrhages.^{151,184} Postmortem examination of the lungs revealed vascular congestion, pleural effusions, and parenchymal hemorrhages.^{184,215}

Gastrointestinal hemorrhage, vomiting, and diarrhea occur frequently.²⁵⁶ At autopsy, edema and hemorrhage of the bowel wall occur.⁴⁷ These changes may be partly a result of the regional ischemia of splanchnic blood vessels and resultant hypoperfusion and hypoxia. Increased bowel wall edema and bleeding predispose to the release of bacteria into the bloodstream from the gut, causing focal microvascular changes in the intestinal villi, leading to bowel wall anoxia and further injury.⁸⁶ Liver injury occurs commonly and is not clinically manifest until the second or third day after the temperature increase.^{150,256} Centrilobular changes, such as widening of central veins and adjacent sinusoids and pooling of blood, and varying degrees of hepatocellular degeneration are demonstrated on liver biopsy. Repeat biopsies demonstrated that these changes resolve as the patient recovers.¹⁵⁰ In other cases, only congestion and fatty infiltration are reported.⁴⁷

Neuropsychiatric impairment is, by definition, present in all cases of heatstroke, the duration of altered consciousness correlates significantly with mortality.^{13,256} Autopsy studies demonstrate a variety of structural and microscopic CNS injuries. Edema and venous congestion are evident. The number of cortical neurons is reduced, with concomitant glial proliferation. Cerebellar Purkinje cell deterioration is marked. The hypothalamus appears to be relatively spared, with limited edema of the neuronal nuclei. Hemorrhages occur throughout the brain.^{47,184,256} Carotid artery vasoconstriction occurs in response to heating in an in vitro model using the carotid arteries of rabbits to elucidate the mechanism of ischemia and injury in heatstroke.²⁰⁵ Heatstroke-induced cerebral ischemia is associated with increased glutamate release, activation of cerebral dopaminergic neurons causing dopamine overload, and gliosis. These changes are attenuated by induction of hypothermia in an animal model.⁵⁰

Reports of magnetic resonance imaging (MRI) of brains of patients recovering from heatstroke describe radiographic findings, including hemorrhagic and ischemic abnormalities of the cerebrum and cerebellum, delayed cerebellar atrophy, central pontine myelinolysis, vascular infarcts, and medial thalamic lesions, which correspond anatomically to the paraventricular nucleus.^{20,191,192} The paraventricular nucleus is involved with core temperature regulation via the hypothalamic–pituitary–adrenal axis.¹⁹ The clinical symptoms of dysphagia, quadriparesis, wasting extrapyramidal

syndrome, and pancerebellar syndrome have corresponding MRI findings.⁴ Persistent cerebellar dysfunction occurs, as does lower motor neuron damage, manifested by areflexia and muscle wasting.^{70,171} Abnormal nerve conduction studies are documented.¹⁴⁴ Higher cortical functions may be spared in survivors or may be reversible when they occur.^{83,174,194} Permanent neurologic sequelae are correlated with the degree and duration of hyperthermia.

Acute kidney injury (AKI) was a major cause of death in heatstroke victims before the advent of hemodialysis.^{249,283} In addition to the direct effects of heat, volume depletion, and hypotension, myoglobinuria secondary to rhabdomyolysis results in further renal tubular injury. This is especially common in an agitated or exercising patient.^{54,102,224} The mechanism by which myoglobin contributes to AKI remains controversial. At autopsy, the kidneys are enlarged, with extensive petechial hemorrhage.¹⁸⁴ Acute tubular necrosis is demonstrated on biopsy. In exertional heatstroke with AKI, renal hemodynamics are compromised because of increased vasoconstrictive hormones, such as catecholamines, renin, aldosterone, and endothelin-1, and decreased vasodilatory hormones, such as prostaglandin E₂.¹⁷⁶

Bleeding is associated with significant morbidity and mortality in many cases of heatstroke. The etiology of coagulation disturbances in patients with heatstroke appear to be multifactorial. Elevation of the prothrombin time may occur within 30 minutes of temperature elevation and is attributed to direct heat injury of clotting factors.¹⁶ Liver damage may significantly contribute to the coagulation disturbances, although this does not manifest as rapidly.^{16,206,227} Two patients with severe liver failure secondary to heatstroke received liver transplantation; both died after chronic rejection.²⁴⁰ A third patient with extensive liver cell necrosis as a consequence of heatstroke was referred for consideration of liver transplantation but recovered completely with supportive therapy.⁹⁹ Evidence of diffuse capillary basement membrane injury is demonstrable by electron microscopy and is thought to precipitate consumptive coagulopathy in severe cases of heatstroke.^{47,261} Thrombocytopenia is very common and occurs within 30 minutes of onset of heatstroke, frequently in the absence of other evidence of disseminated intravascular coagulation. Direct thermal injury leading to decreased platelet survival and megakaryocyte damage may play a role (Table 30–6).^{184,206}

TABLE 30–6. Physiologic and Clinical Manifestations of Heatstroke

Cardiovascular

- Hypodynamic states in elderly adults
- Hyperdynamic states in young, healthy individuals
- Electrocardiogram
- Nonspecific
- Widening of QRS because of an underlying abnormality (cocaine toxicity, hyperkalemia associated with rhabdomyolysis)

Central nervous system

- Altered mental status
- Irritability, confusion, ataxia, seizures, coma

Proteinuria

Oliguria

Acute tubular necrosis

Interstitial necrosis

ALT = alanine aminotransferase; AST = aspartate aminotransferase; CPK = creatine phosphokinase; LDH = lactate dehydrogenase; PT = prothrombin time; PTT = partial thromboplastin time.

Clinical Findings in Heatstroke

Clinical evaluation of a hyperthermic patient begins with careful assessment of the vital signs. Vital sign abnormalities

commonly include tachycardia with heart rates greater than 130 beats/min, hypotension, and tachypnea with the respiratory rates often above 30 breaths/min. Most importantly, temperature is elevated. After cooling, there is often a secondary rise in temperature that suggests persistent disturbances of thermoregulation.¹⁸⁴

Neurologic examination reveals a delirious, comatose, or seizing patient. Pupils may be normal, fixed and dilated, or pinpoint. Decerebrate or decorticate posturing may be evident. Muscle tone is increased, normal, or flaccid. The skin may be hot and dry or diaphoretic. Nasal and oropharyngeal bleeding may be present as a consequence of the acute coagulopathy. Examination of the lungs is often nonspecific, although heatstroke victims are at risk of acute respiratory distress syndrome (ARDS) as a primary event associated with capillary endothelial damage or after overly aggressive fluid resuscitation. Cardiac auscultation may reveal a flow murmur secondary to high cardiac output or a right ventricular gallop. Neck vein distension indicates increased CVP. Jaundice suggests hepatic injury and occurs on the second or third day after the onset of heatstroke.⁴⁹ Nasogastric aspiration or rectal examination may demonstrate gross bleeding. A petechial rash develops, probably secondary to capillary endothelial damage.

Laboratory Findings of Heatstroke

Lactate dehydrogenase (LDH) rises as a consequence of diffuse tissue injury. Early rises in alanine aminotransferase (ALT) and aspartate aminotransferase (AST), which peak at 48 hours, are indicators of the liver damage that occurs during heatstroke.¹⁵⁰ Muscle enzymes were elevated in all patients in a study of exertional heatstroke²⁵⁶ and in 86% of patients in one study of nonexertional heatstroke.¹⁰⁸ Nonspecific ST- and T-wave changes on ECG are common. Myocardial enzyme elevation occurs and correlates with ECG changes.¹⁵¹ Results of lumbar puncture are nonspecific, are often normal, or may demonstrate elevated CSF protein and lymphocytosis.²⁵⁶

Other laboratory parameters are affected by heatstroke. Salt and water depletion leads to hemoconcentration in patients exposed to elevated temperatures for a period of time. Hypokalemia is common, with potassium deficits as great as 500 mEq occurring during the early period of heat exposure. Arterial blood gas analysis may show a respiratory alkalosis secondary to direct stimulation of the respiratory center by heat or a metabolic acidosis with an elevated lactate concentration.^{61,265} Metabolic acidosis is the most frequent acid–base disturbance, either alone or part of a mixed picture. The prevalence of metabolic acidosis correlates with the degree of hyperthermia; 95% of patients demonstrated metabolic acidosis when the body temperature exceeded 107.6°F (42°C).²⁸

Hypophosphatemia is common and is attributed to respiratory alkalosis, which causes intracellular shifts of phosphate. However, eight of ten heatstroke patients developed hypophosphatemia, and none was alkalemic.²⁷ The hypophosphatemia in these patients was associated with increased phosphaturia and decreased tubular reabsorption of phosphorus, a finding that reversed after cooling.¹⁵⁸ Renal tubular damage may also lead to phosphate depletion.¹¹² Phosphate and potassium are elevated when significant muscle injury has occurred. Calcium is normal or low, the latter secondary to binding to damaged muscle tissue. Later, hypercalcemia occurs, possibly as a result of release of this bound calcium.^{95,178}

Significant alterations occur in lymphocyte subsets in heatstroke victims. One study reported an increased ratio of T-suppressor to T-cytotoxic cells, as well as increased natural killer cells. There was a significant decrease in the percentages of T and B cells and T-helper cells. These changes correlate with the degree of hyperthermia.^{25,29} Catecholamines are increased in heatstroke¹ and may affect the distribution of the lymphocyte subsets.²⁵ It is possible that the increased susceptibility to infection described in heatstroke and the alterations in lymphocyte populations are related.²⁵

Effects of Xenobiotics in Heatstroke

Xenobiotics predispose the individual to heatstroke by two primary mechanisms: increased production of heat as a result of xenobiotic action and interference with the body's ability to dissipate heat because of pharmacologic or toxicologic effects on thermoregulatory centers (Table 30–5). Xenobiotic interactions may cause life-threatening increases in temperature, such as the combination of monoamine oxidase inhibitors with meperidine or dextromethorphan resulting in serotonin toxicity. The uncoupling of oxidative phosphorylation by salicylate, pentachlorophenol, or dinitrophenol leads to the release of metabolic energy as heat rather than trapping that energy in the form of high energy phosphate bonds in ATP. Sympathomimetics may increase heat production by increasing physical activity.

During heat stress, vasodilation leads to increased cutaneous blood flow, resulting in an increased cardiac output. Parasympathetic stimulation results in increased sweating. Xenobiotics that impair these physiologic mechanisms for heat dissipation predispose the individual to heatstroke. Xenobiotics with anticholinergic effects, such as antihistamines, cyclic antidepressants, and antipsychotics, interfere with sweating. Heatstroke as a result of oligohidrosis is reported for zonisamide and topiramate.^{160,210} The mechanism is postulated to concern the inhibition of carbonic anhydrase, an enzyme associated with eccrine sweat gland function. Sympathomimetics stimulate α -adrenergic receptors, impairing vasodilation. Antihypertensives and antianginals (most notably calcium channel blockers and β -adrenergic antagonists) with negative inotropic and chronotropic effects impair the ability of the heart to meet the output requirements of increased skin blood flow. Diuretic-induced salt and water depletion also limits cardiac output. Antipsychotics cause hypothalamic depression,

altering the normal CNS response to heat stress. Finally, xenobiotics such as ethanol, opioids, and sedative–hypnotics impair normal behavioral responses, and heat-related discomfort may go unnoticed.²⁹²

Heatstroke and Subsequent Heat Intolerance

Whether heatstroke victims are subsequently unable to adapt to exercise in a hot environment remains unclear. Is the heatstroke victim genetically predisposed to heat intolerance, or does heatstroke occur as a result of environmental and host factors? Several studies suggest that heatstroke leads to persistent heat intolerance. These studies often use a single heat intolerance test.^{81,255,257,258} A study of 10 previous heatstroke victims showed no difference in acclimatization responses, thermoregulation, whole-body sodium and potassium balance, sweat gland function, and blood values when compared with control participants.¹² The rate of recovery from exertional heatstroke probably differs among individuals. In this study, one of 10 patients was found to have recurrent heat intolerance 12 months after the study.¹² Resolution of heat intolerance was delayed for 5 months in an individual who had experienced heatstroke twice.¹⁴⁹

Treatment of Heatstroke

Management must focus on the early recognition of hyperthermia. Body temperatures above 106°F (>41.1°C) place the patient at great risk for end-organ injury. Rapid cooling is the first priority and is associated with improved outcomes. Cooling that is delayed allowing body temperatures to remain above 102.2°F (38.9°C) for more than 30 minutes is associated with a high morbidity and mortality. In one report of the Chicago heat wave of 1995, only one patient of 58 victims was cooled within 30 minutes, resulting in an in-hospital mortality rate of 21% and an additional 28% mortality rate within 1 year.⁷¹ Cooling by covering in ice water was twice as rapid in lowering the core temperature as was cooling by using an evaporative spray.¹¹ Ice water immersion results in faster cooling compared with all of the evaporative cooling methods in some studies.^{60,88,96} A more recent report of endovascular cooling using a heat exchange balloon catheter demonstrated dangerously lengthy cooling times and inadequate cooling measures.¹⁹³

Successful treatment requires adequate preparation. Equipment needed for rapid cooling should always be readily available in the emergency department and includes fans, ice, and tubs for immersion. En route to the hospital, the patient's clothes should be removed, and the patient should be covered with ice, if available, and water-soaked sheets. Respiration and cardiovascular status should be stabilized and monitored. Oxygen should be administered. The cause of the heatstroke should be determined and appropriate measures initiated immediately. Xenobiotics, such as antihistamines, butyrophenones, and phenothiazines, and physical restraints that interfere with heat dissipation, such as camisoles and strait jackets, should not be used.¹⁰⁹ Light hand and foot restraints should be used to protect the patient from self-harm. If light restraints are used, the patient should be monitored continuously. A patient who is hyperthermic in the setting of ethanol or sedative–hypnotic withdrawal should be treated with a benzodiazepine.¹⁰⁸ The patient should never be confined to a small, unventilated seclusion room. Adequate cooling, hydration, sedation, and electrolytes and substrate repletion should be ensured.¹⁰⁶

In the emergency department, appropriate laboratory studies should be performed and an IV line inserted. Administration of 100 mg of thiamine should be considered. A rectal probe should be placed for continuous temperature monitoring. The patient should be immersed in an ice bath with a fan blowing over the patient if possible. In addition to the ice bath, iced gastric lavage may be effective.

Agitation, seizures, and cardiac dysrhythmias must be managed while cooling is accomplished. Benzodiazepines are the treatment of choice for agitation and seizures. Heatstroke patients may have significant volume needs, depending on the amount of fluid lost before the onset of heatstroke. Hypotension should be treated with fluids and cooling. Volume repletion should be monitored carefully by parameters such as blood pressure, pulse, CVP, and urine output. As the temperature returns to normal, the hypotension may resolve if significant volume deficits are not present.^{53,157,159} In patients with myoglobinuria, an attempt should be made to increase renal blood flow and urine output. The use of sodium bicarbonate and mannitol in the prevention of acute tubular necrosis in these cases is controversial.^{80,95,237}

Phenothiazines and butyrophenones should not be used because they may depress an already altered mental status, may produce hepatotoxicity in a compromised liver, lower the seizure threshold,²⁴ cause acute dystonic reactions, exacerbate hypotension, and interfere with thermoregulation and cooling by affecting the hypothalamus. However, although phenothiazines and butyrophenones may theoretically reduce shivering and the possibility of rebound hyperthermia, their onset of action is slow.²¹⁴ When shivering occurs during cooling, we recommend the judicious use of a benzodiazepine. In addition, benzodiazepines treat ethanol and sedative–hypnotic withdrawal and cocaine toxicity, common causes of hyperthermia.

There is no role for antipyretics in the management of heatstroke. Aspirin and acetaminophen lower temperature by reducing the hypothalamic set point, which is only altered in a patient febrile from inflammation or endogenous pyrogens.^{72,126} Heatstroke, however, occurs when cooling mechanisms are overwhelmed and the hypothalamic

thermoregulatory set point is not disturbed.¹⁷

Dantrolene is the preferred drug in the treatment of malignant hyperthermia (Antidotes in Depth: A21).^{139,285} It acts directly on skeletal muscle and either inhibits the release of calcium or increases calcium uptake through the sarcoplasmic reticulum.³² Its usefulness has not been demonstrated in other conditions associated with hyperthermia, and there is no evidence to support its administration for other conditions.⁷ In a prospective, randomized, double-blind, placebo-controlled study of 52 patients with heatstroke, IV dantrolene at 2 mg/kg of body weight did not alter cooling time.²⁶ There was no significant difference in the mean number of hospital days necessitated by heatstroke victims who received dantrolene and cooling versus those who received cooling alone. Dantrolene may influence central dopaminergic metabolism in patients with neuroleptic malignant syndrome by affecting calcium-triggered neurotransmitter release in the CNS; however, further study is required.²¹² Anecdotal reports of the efficacy of dopamine agonists such as bromocriptine and amantadine have appeared in descriptions of neuroleptic malignant syndrome.¹⁹⁰ No drug therapy should delay the institution of aggressive external cooling (Table 30–7).

TABLE 30–7. Management of Heatstroke

Preparation

Ice and cooling fans available in emergency department

Monitor weather reports

Alert media

On arrival

Rapid cooling

Clear airway and administer oxygen

Cover with ice and water-soaked sheets

Stabilize respiratory and cardiovascular status

Cool as rapidly as possible

Intravenous access

Consideration of 0.5–1.0 g/kg of dextrose and 100 mg of thiamine

Benzodiazepines for agitation, shivering, seizures

Continuous monitoring

Remove from ice bath at 101°F (38.3°C)

Watch for rebound hyperthermia

Cautions

Antipsychotics may have serious adverse effects

Antipyretics do not work

Cooling blankets alone are inadequate

SUMMARY

- Xenobiotics may disturb normal thermoregulation and result in the abnormal conditions of hyperthermia or hypothermia. These disturbances of homeostasis present significant clinical management challenges.
- Hypothermia and heatstroke are preventable conditions.

- Immediate and aggressive cooling is imperative in heatstroke. Near-normal body temperature should be achieved within 30 minutes from onset of heatstroke.
- Rewarming of the patient with hypothermia and a stable cardiac rhythm can often be successfully accomplished with patience and without extracorporeal methods.
- Climate change causing increasingly hot weather demands municipal preparedness and public education efforts to prevent deaths during hot conditions.

31 REPRODUCTIVE AND PERINATAL PRINCIPLES

Jeffrey S. Fine

Reproductive and perinatal principles in toxicology are derived from basic science and are applied to clinical practice. This chapter reviews several principles of reproductive medicine that have implications for toxicology, including the physiology of pregnancy and placental xenobiotic transfer, the effects of xenobiotics on the developing fetus and the neonate, and the management of overdose in pregnant women.

One of the most dramatic effects of exposure to a xenobiotic during pregnancy is the birth of a child with congenital malformations. Teratology, the study of birth defects, has principally been concerned with the study of physical malformations. A broader view of teratology includes “developmental” teratogens—xenobiotics that induce structural malformations, metabolic or physiologic dysfunction, or psychological or behavioral alterations or deficits in the offspring, either at or after birth.²⁷⁴ Only 4% to 6% of birth defects are attributable to known pharmaceuticals or occupational and environmental exposures.^{44,274}

Reproductive effects of xenobiotics may occur before conception. Female germ cells are formed in utero; adverse effects from xenobiotic exposure can theoretically occur from the time of a woman’s own intrauterine development to the end of her reproductive years. An example of a xenobiotic that had both teratogenic and reproductive effects is diethylstilbestrol (DES), which caused vaginal or cervical adenocarcinoma (or both) in some women who had been exposed to DES in utero and also had effects on fertility and pregnancy outcome.^{26,33}

Men generally receive less attention with respect to reproductive risks. Male gametes are formed after puberty; only from that time on are they susceptible to xenobiotic injury. An example of a xenobiotic affecting male reproduction is dibromochloropropane, which reduces spermatogenesis and, consequently, fertility. In general, much less is known about the paternal contribution to teratogenesis.³³⁶

Occupational exposures to xenobiotics are potentially important but are often poorly defined. In 2004, it was estimated that there were 41 million women of reproductive age in the workforce.³¹³ Although approximately 90,000 chemicals are used commercially in the United States, only a few thousand of them have been specifically evaluated for reproductive toxicity. Many xenobiotics have teratogenic effects when tested in animal models, but relatively few well-defined human teratogens have been identified (Table 31–1).²⁸⁶ Thus, most tested xenobiotics do not appear to present a human teratogenic risk, but most xenobiotics have not been tested. Some of the presumed safe xenobiotics may have other reproductive, nonteratogenic toxicities. Several excellent reviews and online resources are available.^{45,104,238,249,274,286}

TABLE 31–1. Known and Possible Human Teratogens

<i>Teratogenic</i>	<i>Reported Effects</i>	<i>Comments</i>
Alkylating agents (eg, busulfan, chlorambucil, cyclophosphamide, mechlorethamine, nitrogen mustard)	Growth retardation, cleft palate, microphthalmia, hypoplastic ovaries, cloudy corneas, renal agenesis, malformations of digits, cardiac defects, other anomalies	10–50% malformation rate, depending on the agent. Cyclophosphamide-induced damage requires cytochrome P450 oxidation.
Aminopterin, methotrexate (amethopterin)	Hydro- or microcephaly, meningoencephalocele, anencephaly, abnormal cranial ossification; cerebral hypoplasia; growth retardation; eye, ear, and nose malformations; cleft palate; malformed extremities or fingers; reduction in derivatives of first branchial arch; developmental delay ¹²²	Folate antagonists inhibit dihydrofolate reductase. High rate of malformations.
Amiodarone	Transient neonatal hypothyroidism, with or without goiter; hyperthyroidism	Amiodarone contains 39% iodine by weight. Small to moderate risk from 10 weeks to term for thyroid dysfunction.
Androgens	Virilization of the female external genitalia; clitoromegaly, labioscrotal fusion	Dose dependent. Stimulates growth of sex steroid receptor-containing tissue.
Angiotensin-converting enzyme inhibitors and angiotensin II type 1 receptor inhibitors	Fetal or neonatal death, prematurity, oligohydramnios, neonatal anuria, IUGR, secondary skull hypoplasia, limb contractures, pulmonary hypoplasia	Significant risk of effects related to chronic fetal hypotension during second or third trimester. If used during early pregnancy, can be switched during first trimester. ^{10,11,44}
Carbamazepine	Upwarding palpebral fissures, epicanthal folds, short nose with long philtrum, fingernail hypoplasia, developmental delay, NTD ¹⁴⁴	1% risk for NTD. Risk of other malformations is unquantified but may be significant for minor anomalies. Risk is increased in setting of therapy with multiple anticonvulsants, particularly valproic acid. Mechanism may involve an epoxide intermediate. High-dose folate is recommended to prevent NTDs.
Carbon monoxide	Cerebral atrophy, intellectual disability, microcephaly, convulsions, spastic disorders, intrauterine death	With severe maternal poisoning, high risk for neurologic sequelae; no increased risk in mild exposures.
Cocaine	IUGR, microcephaly, neurobehavioral abnormalities, vascular disruptive phenomenon (limb amputation, cerebral infarction, visceral or urinary tract abnormalities)	Vascular disruptive effects because of decreased uterine blood flow and fetal vascular effects from first trimester through the end of pregnancy. Risk for major disruptive effects is low.
Corticosteroids	Cleft palate, decreased birth weight (up to 9%) and head circumference (up to 4%)	Low risk. Most information related to prednisone or methylprednisolone.
Coumadin	Fetal warfarin syndrome: nasal hypoplasia, chondrodysplasia punctata, brachydactyly, skull defects, abnormal ears, malformed eyes, CNS malformations, microcephaly, hydrocephalus, skeletal deformities, intellectual disability, spasticity	10%–25% risk of malformation for first trimester exposure, 3% risk of hemorrhage, 8% risk of stillbirth. Bleeding is an unlikely explanation for effects produced in the first trimester. CNS defects may occur during the second or third trimesters and may be related to bleeding. ^{140,143}
Diazepam	Cleft palate, other anomalies	Controversial association, probably low risk. ^{45,46,145} Risk may extend to other benzodiazepines. Also risk for neonatal sedation or withdrawal after maternal use near delivery.
Diethylstilbestrol (DES)	Female offspring: vaginal adenosis, clear cell carcinoma, irregular menses, reduced pregnancy rates, increased rate of preterm deliveries, increased perinatal mortality and spontaneous abortion Male offspring: epididymal cysts, cryptorchidism, hypogonadism, diminished spermatogenesis	A synthetic nonsteroidal estrogen that stimulates estrogen receptor-containing tissue and may cause misplaced genital tissue with a propensity to develop cancer. A 40%–70% risk of morphologic changes in vaginal epithelium. Risk of carcinoma is approximately one in 1000 for exposure before the 18th gestational week. Most patients exposed to DES in utero can conceive and deliver normal children.
Ethanol	FAS: pre- or postnatal growth retardation, intellectual disability, fine motor dysfunction, hyperactivity, microcephaly, maxillary hypoplasia, short palpebral fissures, hypoplastic philtrum, thinned upper lips, joint, digit anomalies	FAS in 4% of offspring of women with alcoholism consuming ethanol above 2 g/kg/d (6 oz/d) over the first trimester. There may be a threshold for effects, but a safe dose has not been identified. Partial expression or other congenital anomalies. Increased incidence of spontaneous abortion, premature delivery, and stillbirth; neonatal withdrawal.
Fluoxazole	Brachycephaly, abnormal facies, abnormal calvarial development, cleft palate, femoral bowing, thin ribs and long bones, arthrogryposis, and congenital heart disease	Risk related to high-dose (400–800 mg/d), chronic, parenteral use. Single 150-mg oral dose probably safe.
Indomethacin	Premature closure of the ductus arteriosus; in premature infants, oligohydramnios, anuria, intestinal ischemia	NSAIDs generally labeled as category B. However, there is concern when used after 31–32 weeks gestation and for more than 48 hours or immediately before delivery. Risk may extend to other NSAIDs.

Iodine and iodine-containing products	Thyroid hypoplasia after the 8th week of development	High doses of radioiodine isotopes can additionally produce cell death and mitotic delay. Tissue and organ-specific damage depends on the specific radioisotope, dose, distribution, metabolism, and localization.
Lead	Lower scores on developmental tests	Higher risk when maternal lead is >5 µg/dL. ¹⁶
Lithium carbonate	Ebstein anomaly	Low risk.
Methimazole	Aplasia cutis, skull hypoplasia, dystrophic nails, nipple abnormalities, hypo- or hyperthyroidism	Small risk of anomalies or goiter with first trimester exposure. Hypothyroidism risk after 10 weeks of gestation.
Methyl mercury, mercuric sulfide	Normal appearance at birth; cerebral palsylike syndrome after several months; microcephaly, intellectual disability, cerebellar symptoms, eye or dental anomalies	Inhibits enzymes, particularly those with sulfhydryl groups. Of 220 babies born after the Minamata Bay exposure, 13 had severe disease. Mothers of affected babies ingested 9–27 ppm of mercury; greater risk with ingestion at 6–8 months' gestation. In acute poisoning, the fetus is four to 10 times more sensitive than an adult. Pathologically, there are atrophy and hypoplasia of the brain cortex and abnormalities in cytoarchitecture. ^{12,18}
Methylene blue (intraamniotic injection)	Intestinal atresia, hemolytic anemia, neonatal jaundice	This xenobiotic was used to identify twin amniotic sacs during amniocentesis. ¹⁹
Misoprostol	Vascular disruptive phenomena (eg, limb reduction defects); Moebius syndrome (paralysis of 6th and 7th facial nerves)	Synthetic prostaglandin E ₁ analog. Effects mostly observed in women after unsuccessful attempts to induce abortion.
Mycophenolate mofetil	Microtia, orofacial cleft, coloboma, hypertelorism, micrognathia, conotruncal CHD, agenesis of the corpus callosum, esophageal atresia, digital hypoplasia	Immunosuppressive xenobiotic used in transplant recipients, inhibits inosine monophosphate dehydrogenase and blocks de novo purine synthesis in T and B lymphocytes. ^{15,20}
Oxazolidinone-2,4-diones (trimethadione, paramethadione)	Fetal trimethadione syndrome: V-shaped eyebrows; low-set ears with anteriorly folded helix; high-arched palate; irregular teeth; CNS anomalies; severe developmental delay, cardiovascular, genitourinary, and other anomalies	An 83% risk of at least one major malformation with any exposure; 32% die. Characteristic facial features are associated with chronic exposure.
Paroxetine	Cardiovascular malformations, mostly VSD and ASD	Possible small (1%) increased risk. Risk may extend to other member of SSRI class.
Penicillamine	Cutis laxa, hyperflexibility of joints	Copper chelator—copper deficiency inhibits collagen synthesis or maturation. Few case reports; low risk.
Phenytoin	Fetal hydantoin syndrome: microcephaly, intellectual disability, cleft lip or palate, hypoplastic nails or phalanges, characteristic facies—low nasal bridge, inner epicanthal folds, ptosis, strabismus, hypertelorism, low-set ears, wide mouth	Phenytoin has a direct effect on cell membranes and on folate and vitamin K metabolism. May reduce the availability of retinoic acid derivatives or alter the genetic expression of retinoic acid. Epoxide intermediate may play a role in teratogenesis. Effects seen with chronic exposure. A 5%–10% risk of typical syndrome, 30% risk of partial syndrome. Risks confounded by those associated with epilepsy itself and use of other anticonvulsants. Possible increased risk of developing tumors, in particular, neuroblastoma, although the absolute risk is very low.
Polychlorinated biphenyls	Cola-colored children; pigmentation of gums, nails, and groin; hypoplastic, deformed nails; IUGR; abnormal skull calcifications	Cytotoxic xenobiotic. Body residue can affect subsequent offspring for up to 4 years after exposure. Most cases followed high consumption of PCB-contaminated rice oil; 4%–20% of offspring were affected. ¹⁴
Progestins (eg, ethisterone, norethindrone)	Masculinization of female external genitalia	Progestogens are converted into androgens or may have weak androgenic activity. Stimulates or interferes with sex steroid receptors. Effects occur only after exposure to high doses of some testosterone-derived progestins and may be at the rate of <1% of those exposed. Oral contraceptives containing these agents are not thought to present teratogenic risk despite their category X designation.
Quinine	Hypoplasia of lith nerve, deafness, abortion	Effects related to high doses used as abortifacients.
Radiation, ionizing	Microcephaly, intellectual disability, eye anomalies, growth retardation, visceral malformations	Significant doses of radiation from diagnostic or therapeutic sources produce cell death and mitotic delay. There is no measurable risk with X-ray exposures of 5 rads or less at any stage of pregnancy. ^{11,15}
Retinoids (isotretinoin, etretinate, high-dose vitamin A)	Spontaneous abortions; micro- or hydrocephalus; deformities of cranium, ears, face, heart, limbs, liver	Retinoids can cause direct cytotoxicity, alter apoptosis, and inhibit migration of neural crest cells. For isotretinoin, 38% risk of malformations; 80% are CNS malformations. Effects are associated with vitamin A doses of 25,000–100,000 units/day. Exposures below 10,000 units/day present no risk to fetuses. Topical retinoids are not considered a reproductive risk. ²⁴
Smoking	Placental lesions, IUGR, increased perinatal mortality, increased risk of SIDS, neurobehavioral effects such as learning deficits and hyperactivity ^{15,22}	Possible mechanisms include vasoconstriction (nicotine effect); hypoxia secondary to hypoperfusion, CO, and CN; and altered development of neurons and neural pathways via stimulation of nicotinic acetylcholine receptors. ^{23,24}

Streptomycin	Hearing loss	Rare reports. A low-risk phenomenon that could be associated with long-duration maternal therapy during pregnancy.
Tetracycline	Yellow, gray-brown, or brown staining of deciduous teeth, hypoplastic tooth enamel	Effects seen after 4 months of gestation because tetracyclines must interact with calcified tissue. Effects occur in 50% of fetuses exposed to tetracycline and in 12.5% of fetuses exposed to oxytetracycline.
Thalidomide	Limb phocomelia, amelia, hypoplasia, congenital heart defects, renal malformations, cryptorchidism, abducens paralysis, deafness, microtia, anotia	~20% risk for exposure during days 34–50 of gestation.
Trimethoprim	NTD, oral clefts, hypospadias, and cardiovascular defects	~1% risk of NTD for first trimester exposure. Mechanism is folic acid inhibition.
Valproic acid	Spina bifida, ASD, cleft palate, hypospadias, polydactyly, craniosynostosis, cognitive deficits, autism ^{42,100,101}	Risk for spina bifida is ~1%, but the risk for dysmorphic facies may be greater. The mechanism of teratogenicity is unknown. Possible explanations include interference with glutathione, folate, or zinc metabolism or regulation of intracellular pH. Risk is confounded by risks associated with epilepsy itself or use of other anticonvulsants.
Vitamin D	Possible association with supravalvular aortic stenosis, elfin facies, and intellectual disability	Large doses of vitamin D may disrupt cellular calcium regulation. Genetic susceptibility may play a role.

ASD = atrial septal defect; CHD = congenital heart disease; CN = cyanide; CNS = central nervous system; CO = carbon monoxide; FAS = fetal alcohol syndrome; IUGR = intrauterine growth restriction; NSAID = nonsteroidal antiinflammatory drug; NTD = neural tube defect; PCB = polychlorinated biphenyl; SIDS = sudden infant death syndrome; SSRI = selective serotonin reuptake inhibitor; VSD = ventricular septal defect.

Data from Brent RL: Environmental causes of human congenital malformations: The pediatrician's role in dealing with these complex clinical problems caused by a multiplicity of environmental and genetic factors. *Pediatrics*. 2004;113:957–968; Nulman I, Litovskoy Y, Stancovski A, Koren G: Teratogenic drugs and chemicals in humans. Clinical teratology in the age of genomics. *CMAJ*. 2002;167:265–271.

Another type of xenobiotic exposure for a pregnant woman is intentional overdose. Although a xenobiotic taken in overdose may have direct toxicity to the fetus, fetal toxicity frequently results from maternal pulmonary or hemodynamic compromise, further emphasizing the critical nature of the maternal–fetal dyad.

Xenobiotic exposures before and during pregnancy can have effects throughout gestation and may extend into and beyond the newborn period. In addition, the effects of xenobiotic administration in the perinatal period and the special case of delivering xenobiotics to an infant via breast milk deserve particular consideration.

PHYSIOLOGIC CHANGES DURING PREGNANCY THAT AFFECT DRUG PHARMACOKINETICS

Many physical and physiologic changes that occur during pregnancy affect both the absorption and distribution of xenobiotics in the pregnant woman and consequently affect the amount of xenobiotics delivered to the fetus.³⁰⁹

Delayed gastric emptying, decreased gastrointestinal (GI) motility, and increased transit time through the GI tract occur during pregnancy. These changes result in delayed but more complete GI absorption of xenobiotics and, consequently, lower peak plasma concentrations. Because blood flow to the skin and mucous membranes is increased, absorption from dermal exposure may be increased. Similarly, absorption of inhaled xenobiotics may be increased because of increased tidal volume and decreased residual lung volume.

An increased free xenobiotic concentration in the pregnant woman can be caused by several factors, including decreased plasma albumin, increased binding competition, and decreased hepatic biotransformation, during the later stages of pregnancy. Fat stores increase throughout pregnancy and are maximal at about 30 weeks; near term, free fatty acids are released, and along with them the lipophilic xenobiotics that may have accumulated in the lipid compartment are released. The increased concentration of circulating free fatty acids can compete with circulating free xenobiotic for binding sites on albumin.

Other factors may lead to decreased free xenobiotic concentrations. Early in pregnancy, increased fat stores, as well as the increased plasma and extracellular fluid volume, lead to a greater volume of distribution. Increased renal blood flow and glomerular filtration may result in increased renal elimination.

Cardiac output increases throughout pregnancy, with the placenta receiving a gradually increasing proportion of total blood volume. Xenobiotic delivery to the placenta may therefore increase over the course of pregnancy.

These processes interact dynamically, and it is difficult to predict their net effect. The concentrations of many xenobiotics, such as lithium, gentamicin, and carbamazepine, decrease during pregnancy even if the dose administered is unchanged.¹⁰⁸

Although not specifically related to the physiologic changes occurring during pregnancy, the fetus may be exposed to xenobiotics that accumulated in adipose tissue before pregnancy. For example, malformations typically ascribed to retinoid

use occurred in a baby born to a woman whose pregnancy began one year after she discontinued use of the xenobiotic etretinate (retinoic acid).¹⁷¹

XENOBIOTIC EXPOSURE IN PREGNANT WOMEN

Exposure to xenobiotics during pregnancy is common. At some time during pregnancy, as many as 90% of pregnant women take prescription or nonprescription medications other than vitamins and mineral supplements. The most commonly used are analgesics, antipyretics, antimicrobials, and antiemetics.^{17,36,78,217,265} In addition, use of caffeine, tobacco, and alcohol is common. Some pregnant women use xenobiotics to treat a preexisting chronic disease such as epilepsy or a newly diagnosed disease such as deep vein thrombosis. Many women use various prescription and nonprescription xenobiotics before recognizing that they are pregnant.

Pharmaceutical manufacturers are required by law to label their products with respect to use in pregnancy according to standards promulgated by the US Food and Drug Administration (FDA) (Table 31–2).³¹⁴ Similar classification systems have been developed in Sweden and Australia.^{8,255,272} The original intent of the US regulations was to inform practitioners about the nature of the available evidence regarding risk in pregnancy. However, the general impression among prescribing health care practitioners is that the categories refer to teratogenic risk, a hierarchy of harmful effects according to the letter categories and an equivalence of risk within each letter category.^{85,279,280} For example, in the US system, a category C medication is generally considered more dangerous than a category B medication in pregnancy even though category C is the default category for medications about which there is little or no specific information available and for which the risk is unknown. Approximately 90% of medications are classified as category C.¹⁸⁶

TABLE 31–2. Food and Drug Administration Use-in-Pregnancy Ratings^a

Category	Risk to Human Fetus	Example(s)	Basis
A	No known risk	Multiple vitamins	Controlled studies show no risk. Adequate, well-controlled studies in pregnant women do not demonstrate a risk to the fetus, and if animal studies exist, they do not demonstrate a risk.
B	Unlikely risk	Acetaminophen, penicillin	No evidence of risk in humans. Either animal studies show risk but human studies do not, or if no adequate human studies have been done, animal studies show no risk.
C	Unknown risk	Albuterol	Risk cannot be excluded. Animal studies may or may not show risk, but human studies do not exist. However, benefits may justify the potential or unknown risk.
D	Known risk but benefit may outweigh risk	Tetracycline	Positive evidence of risk. Investigational or postmarketing data or human studies show risk to fetuses. Nevertheless, potential benefits may outweigh the potential risk (eg, if the drug is needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective).
X	Known risk but risk significantly outweighs benefit	Isotretinoin	Contraindicated in pregnancy. Studies in animals or humans or investigational or postmarketing reports have shown fetal risk that clearly outweighs any possible benefit to the patient.

^aBased on US Food and Drug Administration. *Specific Requirements on Content and Format of Labeling for Human Prescription Drugs*. 21 CFR Ch. I (4–1–04 ed.) § 301.57.

There is significant discordance between the use-in-pregnancy labeling and the teratogenic risk as determined by clinical teratologists,¹⁸⁶ and the FDA system has been criticized for being too conservative.¹⁰³ Manufacturers may label certain medications as category X even when there is only limited information associating the medication with any adverse fetal or neonatal effects. For example, oral contraceptives generally carry a category X classification even though they are not considered teratogenic; category X is assigned because there is no indication for use of oral contraceptives in pregnancy.¹⁶⁹ Certain medications with a category D classification may cause problems only at certain times during pregnancy. Approximately 6% of pregnant women are prescribed medications that carry a category D or X classification, and 1% are prescribed medications that are definitively considered teratogenic.¹⁸ Even medications that are classified as category D or X may only have a very low risk of teratogenicity or other adverse effect, and exposure to these xenobiotics, even during the first trimester, may not be a sufficient indication to terminate a pregnancy.⁹¹

The difficulty regarding appropriate drug labeling reflects many complex questions regarding the use of medications during pregnancy. How should animal data in general be evaluated? How should animal data be extrapolated to humans? How should the teratogenic risk be defined and quantified for any particular xenobiotic? How should the risk of not treating a particular disease be compared with the risk of using a particular medication to treat that disease? Finally, how should the answers to these questions be communicated to practitioners and the public?²⁸⁰

In an attempt to address many of these problems, the FDA has proposed changes to the labeling of medications for use

in pregnancy and lactation.^{134,169,316} These changes include (1) a concise description and estimate of risk of structural teratogenesis, fetal or infant mortality, and impaired growth or physiologic function; (2) details of animal and human data, in particular information from registries, cohort studies, and case-control studies; and (3) clinical considerations such as risk of the disease (treated or untreated) versus risk of the medication, need for dose adjustment in pregnancy, adverse drug reactions specific to pregnancy, monitoring of drug use and effect, effects on labor and delivery, and neonatal complications. Similar labeling rules are proposed for medication effects in the setting of lactation.

Specific current information on individual xenobiotics can be obtained from local and regional teratogen information services⁷ and published books,^{45,104,274,285} some of which also have online versions.^{219,249,307} Motherisk is a Canadian program that uses accumulated evidence and experience to advise women about their actual risk of using a particular medication or being exposed to a particular xenobiotic in a current or planned pregnancy.^{218,219}

Although most women are concerned about the teratogenic effects of medications, in utero exposure to therapeutic medications can have other pharmacologic effects on newborn infants, such as hyperbilirubinemia or withdrawal syndromes.^{45,81}

Estimates of substance use in pregnancy vary tremendously, depending on the geographic location, practice environment, patient population, and screening method.^{56,174} In the National Survey on Drug Use and Health, approximately 16% of pregnant women smoked cigarettes, 11% drank ethanol, 5% used marijuana, 0.25% used cocaine, and 0.1% used heroin.²⁶⁹ Women tend to decrease their exposure to xenobiotics after they know they are pregnant.^{37,141,145}

PLACENTAL REGULATION OF XENOBIOTIC TRANSFER TO FETUSES

With respect to the transfer of xenobiotics from mother to fetus, the placenta functions in a manner similar to other lipoprotein membranes. Most xenobiotics enter the fetal circulation by passive diffusion down a concentration gradient across the placental membranes. The characteristics of a substance that favor this passive diffusion are low molecular weight (MW), lipid solubility, neutral polarity, and low protein binding.²⁴² Polar molecules and ions may be transported through interstitial pores.³¹⁰

Xenobiotics with an MW greater than 1000 Da do not diffuse passively across the placenta, and this characteristic is used to therapeutic advantage. For example, warfarin (MW, 1000 Da) easily crosses the placenta and causes specific fetal malformations.³²² However, heparin (MW, 20,000 Da), which is too large to cross the placenta, is not teratogenic and, consequently, is the preferred anticoagulant during pregnancy. Most therapeutic medications have MWs between 250 and 400 Da and easily cross the placenta. For example, thiopental is highly lipid soluble and crosses the placenta rapidly. Fetal plasma concentrations reach maternal concentrations within a few minutes. Neuromuscular blockers such as vecuronium are more polar and cross the placenta slowly.⁸⁸

Although ionization is a limiting factor for diffusion, some highly charged molecules can still diffuse across the placenta. Valproic acid (pK_a of 4.7) is nearly completely ionized at physiologic pH, yet there is rapid equilibration across the placental membrane. The small amount of xenobiotic that exists in the nonionized form rapidly crosses the placenta, and as the equilibrium is reestablished, a new, small amount of nonionized xenobiotic becomes available for diffusion.²²³

Fetal blood pH changes during gestation. Embryonic intracellular pH is high relative to the intracellular pH of the pregnant woman. During this developmental stage, weak acids diffuse across the placenta to the embryo and remain there because of “ion trapping.” Many teratogens, such as valproic acid, trimethadione, phenytoin, thalidomide, warfarin, and isotretinoin, are weak acids. Although ion trapping does not explain the mechanism of teratogenesis, it may explain how xenobiotics accumulate in an embryo. Late in gestation, the fetal blood is 0.10 to 0.15 pH units more acidic than the maternal blood; this pH differential may permit weakly basic xenobiotics to concentrate in the fetus during this period.²⁴²

The relative concentrations of protein binding sites in the pregnant woman and fetus also have an impact on the extent of xenobiotic transfer to the fetus.²⁴² As maternal free fatty acid concentrations increase near term, these fatty acids can displace xenobiotics such as valproic acid or diazepam from maternal protein binding sites and make more free xenobiotic available for transfer to the fetus. Fetal albumin concentrations increase during gestation and exceed maternal albumin concentrations by term. Because the fetus does not have high concentrations of free fatty acids to compete for protein binding sites, these sites are available for binding the xenobiotics. At birth, when neonatal free fatty acid concentrations increase two- to threefold, they displace stored xenobiotic from the binding protein. In the cases of valproic acid and diazepam, the elevated concentrations of free xenobiotic have adverse effects on the newborn infant.^{111,143,223,248}

The placenta may also affect xenobiotic presentation to the fetus by ion trapping and xenobiotic metabolism. The placenta blocks the transfer of some positively charged ions such as cadmium and mercury¹²² and may even accumulate them. This barrier does not necessarily protect the fetus, however, because these metal ions interfere with normal placental function and may lead to placental necrosis and subsequent fetal death.²¹⁶

The placenta contains xenobiotic-metabolizing enzymes capable of performing both phase I and phase II reactions (Chaps. 13 and 23). However, the concentration of biotransforming enzymes in the placenta is significantly lower than that

in the liver, and it is unlikely that the level of enzymatic activity is protective for the fetus. Moreover, the fetus may be exposed to reactive intermediates that form during these processes. On the other hand, glutathione may also be present in the placenta and detoxify some of these reactive intermediates.¹⁵⁰

Placental transfer of xenobiotics can have a positive effect when it delivers desired therapies to the fetus. For example, if a fetus is found to have a supraventricular tachycardia or atrial flutter, digoxin can be given to the mother to treat the tachydysrhythmia in the fetus.^{162,263}

EFFECTS OF XENOBIOTICS ON THE DEVELOPING ORGANISM

A basic premise of teratogenicity is that the particular toxic effects of a xenobiotic are determined by the stage of development of the embryo or fetus.^{41,281} Although the fertilized ovum is generally thought to be resistant to toxic insult before implantation,⁴¹ xenobiotics in the fallopian or uterine secretions may prevent implantation of the embryo. Xenobiotic exposure leading to cell loss or chromosomal abnormalities may also lead to loss of the embryo, possibly even before pregnancy has been detected. If the preimplantation embryo survives a xenobiotic exposure, the functional cells usually proceed to normal development.²⁸¹ Teratogens that act in such a manner elicit an “all-or-none response”; that is, the exposed embryo will either die or go on to normal development.

The dose–response curve of environmental xenobiotics can have deterministic (threshold) or stochastic (no threshold) effects.⁴² Mutagenic and carcinogenic events are stochastic phenomena. Teratogenesis is a deterministic phenomenon with a threshold dose below which no effects occur. As the dose of the teratogen increases above the threshold, the magnitude of the effect increases. The effects might be the number of offspring that die or develop malformations or the extent or severity of malformations. Radiation is one agent that has both deterministic effects (eg, microcephaly and growth retardation) and stochastic effects (induction of leukemia). Strictly speaking, teratogenic effects are those that occur at doses that do not cause maternal toxicity because maternal toxicity itself might be responsible for an observed adverse or teratogenic effect on the developing organism.⁴¹

Organogenesis occurs during the embryonic stage of development between days 18 and 60 of gestation. Most gross malformations are determined before day 36, although genitourinary and craniofacial anomalies occur later.⁴¹ The period of susceptibility to teratogenic effects varies for each organ system (Fig. 31–1). For instance, whereas the palate has a very short period of sensitivity, lasting approximately 3 weeks, the complete development of the central nervous system (CNS), including neurogenesis and differentiation, arborization, synaptogenesis and synaptic organization, and myelination and gliogenesis, remains susceptible throughout the fetal period and into the neonatal period and infancy.

FIGURE 31-1. Critical periods of human prenatal development. CNS, central nervous system. (Modified with permission from Moore KL, Persaud TVN, Torchia MG: *Before We Are Born: Essentials of Embryology and Birth Defects*. 8th ed. Philadelphia: Saunders; 2013.)

Theoretically, knowing the exact time of teratogen exposure during gestation would allow prediction of a teratogenic effect; this is true in animal models, where the dose and time of exposure can be strictly controlled. It is also true for thalidomide in which different limb anomalies are specifically related to exposures on particular days of gestation.²⁸¹ In many clinical situations, for xenobiotics administered either for a short course or chronically, relating teratogenicity to a particular xenobiotic exposure is difficult because the exact time of conception and the exact time of exposure are unknown. This is particularly true when the primary exposure precedes the identification of pregnancy but there is secondary or ongoing exposure during pregnancy as xenobiotic is redistributed from tissue storage sites.¹⁷¹

During the fetal period, formed organs continue their cellular differentiation and grow to functional maturity. Exposure to xenobiotics such as cigarettes and their toxic constituents during this period generally lead to growth retardation. Teratogenic malformations or death may still occur as a result of disruption or destruction of growing organs, as has resulted from exposure to angiotensin-converting enzyme inhibitors during the second and third trimesters.³⁰

Another concern during the fetal period is the initiation of carcinogenesis. Significant cellular replication and proliferation lead to a dramatic growth in size of the organism. At the same time, when the fetus is exposed to xenobiotics, development of biotransformation systems may expose the organism to reactive metabolites that might initiate tumor formation. Some tumors, such as neuroblastoma, appear so early in postnatal life that their prenatal origin is suggested. In pregnant rats given ethylnitrosourea during the embryonic period, lethal or teratogenic effects occur.²⁵⁰ If ethylnitrosourea is administered during the fetal period, there is an increased incidence of tumors in the offspring. Clear cell vaginal and cervical adenocarcinomas occur in the female offspring of women exposed to DES during pregnancy.³³

MECHANISMS OF TERATOGENESIS

Cytotoxicity is one mechanism of teratogenesis and is the characteristic result of exposure to alkylating or chemotherapeutic agents. Aminopterin, for example, inhibits dihydrofolate reductase activity and leads to suppression of mitosis and cell death. If exposure to a cytotoxic xenobiotic occurs very early in development, the conceptus may die, but sublethal exposure during organogenesis may result in maldevelopment of particular structures. There is evidence that after cell death, the remaining cells in an affected region may try to repair the damage caused by the missing cellular elements. This “restorative growth” may lead to uncoordinated growth and exacerbate the original malformation.

In the case of the cytotoxics, the mechanism of action is understood, although it is not always clear why particular xenobiotics affect particular structures. With other xenobiotics, the structural effects have a clearer relationship to the site of action. For instance, when corticosteroids are administered in large doses to some experimental animals during the period of organogenesis, malformations of the palate occur. Glucocorticoid receptors are found in high concentrations in the palate of the developing mouse embryo.²⁴³ Corticosteroid exposure can also cause cleft palate in humans at a low frequency.^{236,285}

Caloric deficiency is not considered teratogenic during the period of organogenesis; however, specific nutritional or vitamin deficiencies can be. In particular, there is an increased incidence of neural tube defects (anencephaly and spina bifida) associated with dietary folate deficiency, although the specific mechanism of teratogenesis is unknown. To ensure that all women of childbearing age have adequate folate stores by the time they become pregnant and during their pregnancy and to reduce the number of severe birth defects, it is important for women to have folate supplementation either as vitamin or dietary supplements even before they become pregnant. Because fortification of grain products is considered critical to help accomplish this goal, the FDA requires US manufacturers to add folic acid to enriched breads, cereals, flours, corn meals, pastas, rice, and other grain products.²³⁰

Ethanol affects fetuses both directly and indirectly. The craniofacial malformations that occur in fetal alcohol syndrome (FAS) probably result from the effects of ethanol during the period of organogenesis. Growth retardation may result from direct effects of ethanol on fetal growth or from indirect effects resulting from ethanol-induced maternal nutritional deficiencies.

MANAGEMENT OF ACUTE POISONING IN PREGNANT WOMEN

For most women, pregnancy and the postpartum period are a period of emotional happiness. However, women have a lifetime prevalence of depression that is two to three times higher than men, and for some women, psychiatric illness during pregnancy, particularly depression and anxiety, represents a significant complication. A new first episode or recurrence of major depression occurs in approximately 3% to 5% of pregnant women and 1% to 6% of postpartum women; an additional 5% to 6% of women in each period will have minor symptoms of depression.¹⁰⁷ Overall, these rates of depression are about the same in pregnant and nonpregnant women; however, during the postpartum period, the onset of new episodes of depression may be three times higher than for nonpregnant women. Pregnant teenagers may also be at higher risk of depression in pregnancy.¹⁸⁴

Postpartum “baby blues” are common; typically involve relatively mild symptoms including mood swings, irritability, anxiety and crying spells; and generally resolve by 2 weeks postpartum.¹⁹¹ Postpartum blues do not include suicidal ideation. True depression is manifested by feelings of hopelessness or helplessness and may include suicidal ideation.¹⁹¹ Postpartum psychosis, typically associated with bipolar disorder, is uncommon, but it represents a true psychiatric emergency because there is a high risk of suicide, infanticide, or both.¹⁹¹

Risk factors for perinatal depression include an unplanned pregnancy, ambivalence about the pregnancy, poor social support, marital difficulties, adverse life events, and chronic stressors such as financial problems.^{65,173,319} Of substantial importance is a personal or family history of depression, particularly previous perinatal depression. Discontinuation of antidepressant represents a significant risk for relapse of disease, although relapse is possible even while a woman is receiving an antidepressant. Additional risk factors for depression include miscarriage, stillbirth, and preterm delivery.²⁷⁶

Depression in pregnancy has adverse effects on both the mother and the fetus.³⁵ For the pregnant woman, adverse effects include noncompliance with prenatal care; self-medication with tobacco, alcohol, and drugs; poor sleep; poor appetite; and poor weight gain. In addition, there may be an increased risk of spontaneous abortion, preeclampsia, preterm delivery, and growth retardation. For many of these outcomes, it is difficult to differentiate the contributions from multiple confounding and interacting factors, including psychopathology, socioeconomic status, acute and chronic stressors, smoking, and the use of alcohol and other drugs of abuse. Infants born to women being treated with antidepressant medications are also at risk for neonatal withdrawal symptoms.¹⁵⁸

One of the most extreme outcomes of depression is suicide. Suicidal ideation occurs in about 5% of pregnant women in community samples and up to 20% in women with underlying psychiatric illness.^{184,226} Even so, suicide and suicide attempts during pregnancy are uncommon. Each year a small number of women die during pregnancy or the postpartum

period; 1% to 5% of these pregnancy-related deaths may be the result of suicide.^{54,76,231} Between 2% and 12% of women who attempt or commit suicide may be pregnant.^{157,240,332} Overall, completed suicide occurs less frequently during pregnancy.^{19,184,205} Psychiatric illness, including previous suicide attempts, predisposes to suicide attempts in pregnancy. Acute stressors leading to impulsive acts account for most of the uncompleted suicide attempts; these reasons include loss of a lover, economic crisis, prior loss of children, and unwanted pregnancy, and desire for an abortion.^{72,180,332} Fewer than half of the suicide attempts are specifically related to a pregnancy-related problem.

Women who complete suicide typically have more severe psychiatric illness. In particular, these women are likely to use more violent means of suicide such as hanging or self-inflicted gunshot wounds, although poisonings are a significant contributor to these deaths.²³¹ In addition, substance and alcohol use is a significant contributing factor in many cases; additionally, some pregnancy-related deaths may be secondary to complications of substance use, such as overdose.²³¹ Initiation of child-protection proceedings, particularly in the setting of maternal substance use, may be an additional risk factor for postpartum suicide.²³¹

Ingestion of xenobiotics is the most common method of attempted suicide during pregnancy and the postpartum period.^{65,240,245} There are about 9000 xenobiotic exposures in pregnant women reported to the AAPCC annually, which account for less than 1% of the approximately 1 million reported adolescent and adult exposures. The patterns of xenobiotic exposure are similar to those of adult exposures in general with analgesics being the most common exposure. However, according to AAPCC data, there are relatively more exposures to cleaning substances, pesticides, fumes, and vitamins, but there are relatively fewer exposures to sedative-hypnotics, antidepressants, and cardiovascular agents; the absolute differences are small (Chap. 136). Some of these xenobiotic exposures may be attempts to terminate pregnancy (Chap. 21).²⁴⁰ As with most poisonings overall, the severity of poisoning in pregnant women is typically minor.^{226,231}

In one US national sample, 1659 pregnant women had poisoning-related hospitalizations, representing 0.04% of all hospitalized pregnant women and approximately 10% of injury-related admissions of pregnant women. A total of 244 of these women (15%) delivered their babies during these hospitalizations related to poisoning.¹⁶⁶

In national samples from both the United States and England, approximately 2% to 3% of deaths in pregnancy and the immediate postpartum period follow suicidal poisoning.^{54,231} The AAPCC reports approximately one to two deaths per year in pregnant women, which represents approximately one to two per 1000 AAPCC-reported adult deaths overall, two to four per 1000 deaths in adult women, and approximately one death per 10000 xenobiotic exposures in pregnancy (Chap. 136). In a combined Hungarian series of pregnant women who had suicidal poisonings, 19 of 1044 (1.8%) died.⁷³

Any woman who attempts suicide during pregnancy or the postpartum period should have a psychiatric evaluation after she is medically stabilized. In particular, a growing number of specialized units or teams focus on pregnant and postpartum women and attempt to keep women and infants together in the postpartum period.^{191,231}

Managing any acute overdose during pregnancy provokes discussion of several questions. Is the general management different? Do altered metabolism and pharmacokinetics increase or decrease the woman's risk of morbidity or mortality from a xenobiotic overdose? Is the fetus at risk of poisoning from a maternal overdose? Is there a teratogenic risk to the fetus from an acute overdose or poisoning? Is the use of an antidote contraindicated, or should use be modified? When should a potentially viable fetus be emergently delivered to prevent toxicity? When should termination of a pregnancy be recommended?

As described earlier, physiologic changes during pregnancy affect pharmacokinetics; xenobiotics taken in overdose also have unpredictable toxicokinetics. In any significant overdose during pregnancy, pregnancy-related alterations in pharmacokinetics are unlikely to protect the woman from significant morbidity or mortality.

Although a single high-dose exposure to a xenobiotic during the period of organogenesis might seem analogous to an experimental model to induce teratogenesis, most xenobiotics ingested as a single, acute overdose do not induce physical deformities.⁷⁴ Anticonvulsants are teratogenic and may be ingested in toxic doses, but their teratogenicity is probably related more to chronic exposure. Acute acetaminophen (APAP) toxicity in the first trimester may lead to an increased risk of spontaneous abortion,²⁵³ suggesting a teratogenic effect similar to the all-or-none response described earlier. In general, however, it is extremely difficult to ascribe teratogenicity to a particular xenobiotic exposure based on a single case report. There is, for example, a report of multiple severe congenital malformations in the stillborn fetus of a woman who overdosed on isoniazid during the 12th week of pregnancy.¹⁷⁸ However, because the background incidence of congenital malformations is 3% to 6%, it is almost impossible to determine for a single individual whether a particular exposure is the etiology of observed malformations.⁷⁵ The Budapest Registry of Self-Poisoned Patients uses this construct to screen for possible teratogenic effects of xenobiotics in overdose.^{73,74} Considering the successful outcome of most pregnancies that progress to term after an acute overdose, it is very unlikely that the small risk of teratogenesis would lead to a recommendation for termination of pregnancy after an acute overdose of most xenobiotics.

In general, any condition that leads to a severe metabolic derangement in a pregnant woman is likely to have an adverse impact on her developing fetus. Therefore, the management of overdose in a pregnant woman usually follows the principles outlined in Chap. 4, with close attention paid to the airway, oxygenation, and hemodynamic stability. The use of naloxone

or dextrose has not been specifically assessed in pregnancy but should be guided by the same considerations raised in managing the nonpregnant patient with alterations in respiratory or neurologic function. Opioid-induced respiratory failure in a pregnant patient will lead to fetal hypoxia and adverse effects; opioid withdrawal in a pregnant woman, whether induced by abstinence or the use of naloxone, may adversely affect the fetus or the pregnancy. Consideration of the benefits and risks of the use of naloxone for an opioid-poisoned woman in respiratory distress or coma suggests that reduced morbidity, for both the mother and fetus, may be achieved by the use of carefully titrated doses of naloxone to minimize the likelihood of maternal withdrawal ([Chap. 38](#) and *Antidotes in Depth: A4*).

Gastrointestinal decontamination is frequently a part of the early management of acute poisoning in nonpregnant patients. Gastric lavage is not specifically contraindicated for pregnant patients, and the usual concerns about protecting the airway apply.

There is no specific contraindication to the use of activated charcoal in a pregnant woman. There may be a specific role for whole-bowel irrigation (WBI) in the management of several xenobiotic exposures, particularly in the treatment of iron overdose in pregnancy.³¹⁷ The use of oral polyethylene glycol is safe in pregnant women.²²⁴

Almost all antidotes are designated as FDA pregnancy-risk category C; that is, there is little specific information to guide their use. Ethanol is labeled as category D (positive evidence of risk), although this is presumably related to chronic use throughout pregnancy. Fomepizole, which has replaced ethanol as the preferred antidote for toxic alcohol poisoning, is labeled as category C. Pyridoxine and thiamine are category A xenobiotics; N-acetylcysteine (NAC), magnesium, glucagon, and naloxone are category B xenobiotics.

Thus far, there are no reports of adverse effects on a fetus from antidotal treatment of a poisoned pregnant woman. Conversely, in at least one case, withholding deferoxamine therapy may have contributed to the death of both a woman and her fetus.^{201,302}

ACETAMINOPHEN

APAP is the most common analgesic and antipyretic agents used during pregnancy and is also one of the most common xenobiotic overdoses during pregnancy. There are two published series of acute APAP overdose during all trimesters of pregnancy in addition to multiple casereports.^{24,50,105,119,133,165,177,190,211,239,253,257,258,264,267,270,299,320} Overall, most pregnant women recover from an APAP ingestion without adverse effects to themselves or their babies.

Of 28 women with first trimester exposures who continued their pregnancies, five women with toxic serum APAP concentrations and 14 with nontoxic concentrations delivered full-term newborns; in one case, both the mother and fetus died; and eight women had spontaneous abortions. Five of these eight had toxic serum concentrations and received NAC (one within 8 hours and four between 12 and 17 hours after ingestion).

Of 31 women with second trimester exposures who continued their pregnancies, seven women with toxic serum APAP concentrations and 20 with nontoxic concentrations delivered full-term babies; one woman with a nontoxic serum concentration and one woman who developed hepatotoxicity delivered premature infants; and two women with nontoxic serum APAP concentrations had spontaneous abortions probably unrelated to the overdose.

Of 54 women with third trimester exposures, 15 women with toxic serum APAP concentrations and 26 with nontoxic concentrations delivered full-term babies; eight woman with a toxic serum concentration, four of whom developed hepatotoxicity, and two women with nontoxic concentrations delivered premature infants; two women with severe hepatotoxicity delivered stillborn infants who also showed signs of hepatotoxicity; and one woman with severe hepatotoxicity delivered an infant who died at 34 hours of life.

There are also several case reports of adverse pregnancy outcome in the setting of chronic use of APAP or acute overdose associated with chronic substance use.^{55,133,167,192,253,311} It is difficult to interpret these reports with respect to specific APAP effect because of the confounders of chronic disease, chronic use, or use of additional medications or substances.

Although APAP at recommended doses is considered safe in pregnancy,¹⁸¹ in overdose, it puts the developing fetus at risk. As the cases demonstrate, APAP crosses the placenta to reach the fetus. There may be an increased risk of spontaneous abortion after overdose during the first trimester, particularly in the setting of toxic serum APAP concentrations and delayed NAC therapy.²⁵³ There is also a question about whether overdose during the first trimester can lead to late sequelae, for instance, premature labor.

Some experimental work might explain early pregnancy loss after overdose. APAP prevented the development of preimplantation (two-cell stage) mouse embryos in culture, an effect that was not associated with alterations in glutathione concentrations,¹⁷⁵ and led to abnormal neuropore development in cultured rat embryos.²⁹⁸ These data suggest that APAP may be directly toxic to the immature organism. However, other work reported that similar embryotoxic effects were associated with reductions in glutathione concentrations³²⁷ and that N-acetyl-p-benzoquinoneimine (NAPQI) produced nonspecific toxicity when added to the rat embryo culture medium.²⁹⁸

The fetal liver has some ability to metabolize APAP to a reactive intermediate in vitro. Cytochrome P450 (CYP) activity was detected in intact hepatocytes, as well as in microsomal fractions isolated from the livers of fetuses aborted between 18 and 23 weeks of gestation. This fetal hepatic CYP activity increased between 18 and 23 weeks (the only period studied) but was maximally only 10% of the activity of hepatocytes isolated from adults after brain death.²⁶¹ In two clinical cases, cysteine and mercapturate conjugates were identified in newborns exposed to APAP in utero, suggesting that the fetus and neonate can metabolize APAP through the CYP system.^{177,257} These data suggest that the fetus in utero and the neonate can generate a toxic metabolite. The clinical cases suggest that the fetal liver is susceptible to injury, although whether this fetal hepatotoxicity is related to fetal APAP toxicity, maternal toxicity, or postmortem changes is unclear.

This CYP activity has not been further characterized. However, CYP2E1, one of the cytochromes responsible for APAP metabolism, is present in human fetal tissues as early as 16 weeks of gestation.²¹⁴ CYP3A4 and CYP1A2 are also involved in APAP metabolism but are not present in fetal liver. CYP3A7 is a functional fetal form of the CYP3 family, but its metabolic activity with respect to APAP has not been studied.¹²⁰

The most relevant clinical questions relate to management of overdose during the third trimester. Can APAP overdose lead to premature labor even if a pregnant woman does not have a toxic serum concentration or develop hepatotoxicity? Should a woman be emergently delivered following overdose? Does NAC treatment of the mother help the fetus? What is the appropriate treatment of a neonate exposed to APAP in utero?

The clinical cases may help address the last two questions (Table 31–3). Seven women whose pregnancies were all at less than 36 weeks of gestation, developed hepatotoxicity. Two infants died in utero, and one infant died on the second day of life with evidence of hepatotoxicity. The other four infants experienced problems associated with prematurity but did not develop obvious hepatotoxicity. One of these four had an exchange transfusion and an unexplained death at 3 months of age. Five women whose pregnancies were all at 36 or more weeks of gestation did not develop hepatotoxicity. One infant had an exchange transfusion and did not develop hepatotoxicity but died of sudden infant death syndrome (SIDS) at 5 months of age. One infant received intravenous (IV) NAC and had a transient elevation of aspartate aminotransferase (AST) and prothrombin time. Two infants were not treated, and both did well, although one had a transient elevation of AST. One infant was born 6 weeks after the overdose and was normal.

TABLE 31–3. Reported Cases of Third Trimester APAP Overdose

Gestational Age (wk)	Maternal		Infant		Comment	Reference
	APAP Concentration ($\mu\text{g/mL}$)(time ^a)	AST Peak (IU/L) (time ^a)	APAP Concentration ($\mu\text{g/mL}$)(time ^a)	Hepatotoxicity (Yes/No)		
27	0 (36 hours)	1226 (36 hours)	ND	No	C/S for fetal distress. Infant: mild respiratory distress syndrome.	105
27–28	56 (16 hours)	6226 (96 hours)	ND	Yes	Ingestion over 24 hours. No fetal movements at presentation. PO NAC started at 20 hours. Induced labor at 4 days. Infant: stillborn with diffuse hepatic necrosis. Hepatic APAP 250 $\mu\text{g/g}$.	119
29	160 (10 hours)	4300 (50 hours)	76 (16 hours, cord)	No	Ingestion of aspirin, caffeine, and quinine followed 17 hours later by APAP. Presented in labor. Treated with oral methionine. Spontaneous delivery at 16 hours. Infant: moderate hyaline membrane disease. Peak AST of 86 IU/L (cord). Four whole-blood exchange transfusions. Discharge home at 54 days of life. Died at 106 days; no apparent cause.	177
30	55 (18 hours)	4000 (48 hours)	ND	ND	Maternal chorioamnionitis with delivery at 31 weeks. Respiratory distress syndrome and hyperbilirubinemia.	239
31	40 (26 hours)	13320 (60 hours)	41 (27)	Yes	APAP only. C/S for fetal distress one hour after initial maternal evaluation. Infant's birth weight was 1620 g. Apgar scores 0, 0, 1. ^b Infant died at 34 hours of life. Mother died at 34 hours postingestion. No autopsy of mother or child.	320
32	448 (12 hours)	5269 (48 hours)	0 (84 hours, cord)	No	IV NAC started at 12 hours. Induced delivery at 84 hours. Infant: transient hypoglycemia, mild respiratory distress, mild jaundice. Peak AST of 56 IU/L (day 1 of life).	211, 264
32	166 (4 hours)	"Normal"	ND	ND	Vaginal delivery at term without complications.	70
33	135 (28 hours)	6237 (66 hours)	330 (3 days, cord)	Yes	Oral NAC at 12 hours. Fetal death at 2 days; spontaneous delivery at 3 days. Infant: stillborn with diffuse hepatic necrosis.	253
36	280 (3–4 hours)	"Normal"	217 (6–7 hours, cord)	No	Ingestion of APAP, ethanol, barbiturates. Elective C/S at 6–7 hours. Infant: double-volume exchange transfusion at 18 hours. Discharge at 40 days, "cot death" at 157 days.	257
36	200 (5 hours)	25 (24 hours)	ND	No	Oral NAC (7 time). Infant: spontaneous delivery 6 weeks after ingestion. Normal neonatal course.	50
38	216 (4 hours)	"Normal"	13 (17 hours, cord)	No	NAC (7 route). Infant: normal neonatal course.	165, 267
"Term"	147 (9 hours)	28 (9 hours)	133 (9 hours, 4 hours of life)	No	Infant PT of 44 at 4 hours of life. IV NAC. No problems. AST of 56 IU/L at 4 hours of life.	24
"Term"	89 (11 hours)	326 (35 hours)	144 (11 hours, 4 hours of life)	No	Mother presented in labor at 6 hours. Infant received IV NAC at 4 hours of life. AST of 55 IU/L at 4 hours of life.	270

^aTime after maternal ingestion. ^bApgar scores are at 1, 5, and 10 minutes.

APAP = acetaminophen; AST = aspartate aminotransferase; C/S = cesarean section; IV = intravenous; NAC = N-acetylcysteine; ND = not done or not reported; PO = oral; PT = prothrombin time.

Severe maternal hepatotoxicity that is associated with any sign of fetal distress is an indication for urgent delivery. Although a fetus with prolonged exposure to APAP in utero is at risk of developing severe hepatotoxicity, not all at-risk infants are affected. What role gestational age, maternal disease state, or other maternal factors may play is unknown. Although there are insufficient case data to suggest that APAP overdose per se is an indication for urgent delivery, there may be an indication for urgent delivery when the maternal serum APAP concentration is in the toxic range but hepatotoxicity has not yet developed.³⁰⁶ The clinical cases suggest that significant APAP overdose with or without hepatotoxicity may precipitate premature labor and that even women with nontoxic serum concentrations may be at an increased risk.

In two cases, exchange transfusion was used to treat the exposed neonate. In both cases, the APAP half-life was prolonged, and in neither case was this affected by the transfusion. Disturbingly, these two infants had unexplained deaths at

several months of age. There are currently no data supporting exchange transfusion as therapy for prenatal exposure.

A pregnant woman with acute toxic APAP ingestion should be treated with NAC ([Chap. 35](#) and Antidotes in Depth: A3). This therapy is designed to treat the mother. Maternal hepatotoxicity and delayed NAC therapy are associated with fetal toxicity²⁵³; whether NAC therapy can prevent later sequelae such as premature delivery is unclear. Although NAC did not cross the sheep placenta in vivo²⁸² or the perfused human placenta in vitro,¹⁴¹ NAC was found in cord blood after administration to four mothers before delivery.¹³³ Even if NAC does cross the placenta, whether it prevents fetal hepatotoxicity is unknown because not all exposed fetuses develop hepatotoxicity.

IRON

Iron is also commonly ingested during pregnancy; maternal toxicity is generally greater than fetal toxicity. In two reported cases, normal babies were delivered, although the mothers died.^{233,251} In another case, the mother had severe iron toxicity with acidosis, shock, kidney failure, and disseminated intravascular coagulation but was not treated with deferoxamine because of concerns about its teratogenic risks. Instead, the mother received an exchange transfusion followed 45 minutes later by a spontaneous abortion of the 16-week fetus.^{201,302} Neonatal and cord blood iron concentrations were not elevated. In several cases, pregnant women who had signs and symptoms of iron poisoning and elevated serum iron concentrations were treated with deferoxamine and subsequently delivered normal babies.^{34,155,170,246,275,312}

Although the placenta transports iron to the fetus efficiently,²³ it also blocks the transfer of large quantities of iron. In a sheep model of iron poisoning, only a small amount of iron was transferred across the placenta despite significantly elevated serum iron concentrations.⁷¹

Deferoxamine is an effective antidote for iron poisoning ([Chap. 46](#) and Antidotes in Depth: A7), but it is reported to be an animal teratogen that causes skeletal deformities and abnormalities of ossification (FDA class C pregnancy risk). An animal model observed similar effects but only with doses of deferoxamine that caused maternal toxicity.³⁸ Experimentally, in sheep, deferoxamine was minimally transported across the placenta⁷¹; therefore, the reported fetal effects may be secondary to chelation of essential nutrients (eg, trace metals) on the maternal side of the placenta.³⁰⁶

In clinical case reports of iron overdose for which deferoxamine was used, there have been no adverse effects on the fetus, although most have been either second or third trimester poisonings.^{34,155,170,233,246,275,312} In a case series of 49 patients with iron poisoning during pregnancy, few of the patients exhibited any clinical toxicity other than vomiting and diarrhea; 25 received deferoxamine, most by the oral route.²¹⁰ One woman with a first trimester overdose, eight women with second trimester overdoses, and 12 women with third trimester overdoses were treated with deferoxamine and subsequently delivered full-term infants. One infant whose mother overdosed at 30 weeks of gestation had webbed fingers on one hand. One woman overdosed at 20 weeks had minimal clinical toxicity, received deferoxamine, and delivered a 2.5-kg male infant at 34 weeks of gestation. One woman with a first trimester overdose and two women with second trimester overdoses elected to terminate their pregnancies.

Further support for the safe use of deferoxamine in pregnancy is the experience with its use for pregnant women with thalassemia major. For many years, deferoxamine has been administered as part of the therapy for posttransfusion iron overload without adverse effects.²⁸⁹

Deferoxamine is probably safe for use in pregnant women. Considering the potentially fatal nature of severe iron poisoning, deferoxamine should be administered when signs and symptoms indicate significant poisoning.

Iron overdose may be one of the few specific indications for WBI because iron is not adsorbed to activated charcoal (Antidotes in Depth: A1 and A2). A case report demonstrated elimination of pill fragments after treatment of a pregnant woman with WBI.³¹⁷

CARBON MONOXIDE

Carbon monoxide is the leading cause of poisoning fatalities in the United States. In contrast to iron and most other xenobiotics, when pregnant women are exposed to carbon monoxide, the fetus may be at greater risk of toxicity than the expectant woman. There are reports of both the mother and fetus dying; the mother surviving but the fetus dying; and both the mother and fetus surviving but with an adverse neonatal outcome, primarily brain damage resembling that seen after severe cerebral ischemia.^{51,69,163,187,202,228,317,335} Similar clinical effects have also been observed in animal models.^{87,112,188}

The case literature suggests an increased risk of poor fetal outcome with clinically severe maternal poisoning or significantly elevated carboxyhemoglobin concentrations.^{163,228} Women with minimal symptoms or low concentrations of carboxyhemoglobin have a low risk of fetal toxicity, but a lower limit of exposure without effect has not been specifically defined.¹⁶³

In animal models, under experimental conditions, the fetus has a carboxyhemoglobin concentration 10% to 15% higher

than the mother.^{128,188} After exposure to carbon monoxide, the fetus achieves peak carboxyhemoglobin concentrations 58% higher than those achieved by the mother at steady state, and the time to peak concentration is also delayed compared with that of the mother. Similarly, the elimination of carbon monoxide occurs more slowly in the fetus than in the mother.^{128,187,188} One case report describes such a phenomenon: after 1 hour of supplemental oxygen, the maternal carboxyhemoglobin concentration was 7% and the fetal carboxyhemoglobin concentration was 61% at the time of death in utero.⁹³

Carbon monoxide leads to fetal hypoxia by several mechanisms: (1) maternal carboxyhemoglobin leads to a decrease in the oxygen content of maternal blood, and therefore less oxygen is delivered across the placenta to the fetus, which normally has an arterial PO₂ of only 20 to 30 mm Hg; (2) fetal carboxyhemoglobin causes a decrease in fetal PO₂; (3) carbon monoxide shifts the oxyhemoglobin dissociation curve to the left and decreases the release of oxygen to the fetal tissues (an exacerbation of the physiologic left shift found with normal fetal hemoglobin); and (4) carbon monoxide may inhibit cytochrome oxidase or other mitochondrial functions (Chap. 125).

The treatment for severe carbon monoxide poisoning is hyperbaric oxygen therapy (HBO) (Chap. 125 and Antidotes in Depth: A38). There are questions about the use of HBO in pregnant women because animal models suggest HBO adversely affects the embryo or fetus.^{99,215,273,305} The applicability of these animal models to humans is difficult to assess; many of the animal models used hyperbaric conditions of greater pressures and duration than those clinically used for humans.

Hyperbaric oxygen therapy has been used therapeutically for carbon monoxide poisoning in pregnancy with good results reported, although there are limited data on the long-term follow-up of the children.^{47,98,106,116,129,163,318} One large series reported 44 women who were exposed to carbon monoxide during pregnancy and were treated with HBO, regardless of clinical severity or gestational age: 33 had term births, one had a premature delivery 22 weeks after HBO during an episode of maternal fever, two had spontaneous miscarriages (one 12 hours after severe poisoning and one 15 days after mild poisoning), one delivered a child with Down syndrome, one had an elective abortion, and six were lost to follow-up.⁹³ Details regarding trimester of exposure, maternal carboxyhemoglobin concentration, and severity of symptoms are not available, making it difficult to interpret the reported adverse outcomes. Although HBO appears safe for pregnant women and seems to present little risk to the fetus, it is not clear whether HBO prevents carbon monoxide–related fetal toxicity.

Hyperbaric oxygen therapy should be considered for any pregnant woman exposed to carbon monoxide, especially for a woman with an elevated serum carboxyhemoglobin concentration or any evidence of fetal distress. To allow the fetal carboxyhemoglobin to be eliminated, if HBO therapy is not available, 100% oxygen should be administered to a pregnant woman for five times as long as the time needed for her carboxyhemoglobin concentration to return to the normal range. Thus, if a pregnant woman's carboxyhemoglobin concentration returns to normal in 30 minutes, she should continue to receive 100% oxygen for a total of 150 minutes.

SUBSTANCE USE DURING PREGNANCY

Illicit and licit substance use during pregnancy and its effects on the woman, on the pregnancy, and on the fetal and postnatal development are complex.

With the increased use of cocaine during the latter half of the 1980s and 1990s, there was great interest in determining the effects of cocaine use during pregnancy. As research in this area progressed, many of the critical methodologic issues related to substance use research were highlighted.^{100,140,179,225,337}

Substance-using women often have multiple risk factors for adverse pregnancy outcomes, such as low socioeconomic status, polysubstance use, ethanol and cigarette use, sexually transmitted infections, AIDS, malnutrition, and lack of prenatal care. Lack of prenatal care is highly correlated with premature birth, and smoking is associated with spontaneous abortion, growth retardation, and SIDS.^{152,330} Other factors not specifically related to substance use such as age, race, gravidity, and prior pregnancies also affect pregnancy outcome. Each of these factors represents a significant potential confounding variable when the effects of a particular xenobiotic such as cocaine or marijuana are evaluated during pregnancy and must be controlled for in research design. Many of these factors are also significant confounders in evaluation of postnatal growth and development.

There may be bias in the selection of study subjects. For example, if all the patients are selected from an inner-city hospital obstetrics service, there is potential for overestimating the effects of the xenobiotic being studied. If cohorts are followed over a long time, study subjects are frequently lost to follow-up. Are the ones who continue more motivated, or do they have more problems that need attention?

Categorizing patients into substance-use groups is difficult. Self-reporting of substance use is frequently unreliable or inaccurate, and making determinations about the nature, frequency, quantity (dose), or timing (with respect to gestation) of xenobiotic exposure is difficult. Because substance users frequently use multiple xenobiotics, it may be difficult to categorize subjects into particular xenobiotic-use groups, and patients using different xenobiotics may be grouped together. In fact, there may be no actual xenobiotic-free control groups.

When urine drug screens are used to identify substance users, there is a high probability of false negatives because drug screens reflect only recent use. This factor is particularly important because substance use tends to decrease later in pregnancy, and a negative urine drug screen in the third trimester or at delivery may fail to identify a woman who was using xenobiotics early in pregnancy. Testing for xenobiotics in hair or meconium may improve the accuracy of the analysis with regard to the entire pregnancy.^{39,160}

Another bias involves selection of infants who are exposed to xenobiotics. Evaluating newborns who are “at risk,” show signs of withdrawal, or have positive urine drug screens will miss some exposed infants. When research concerns the neurobehavioral development of children exposed in utero to substances, it is important that the examiners performing the evaluation be blinded to the infants’ xenobiotic exposure category.

Finally, there may be a bias against publishing research that shows a negative or no significant effect.¹⁶¹

Ethanol

Chronic ethanol use during pregnancy produces a constellation of fetal effects. The most severe effects occur in the FAS, which is characterized by (1) intrauterine or postnatal growth retardation; (2) intellectual disability or behavioral abnormalities; and (3) facial dysmorphogenesis, particularly microcephaly, short palpebral fissures, epicanthal folds, maxillary hypoplasia, cleft palate, a hypoplastic philtrum, and micrognathia.^{32,200} A child can be diagnosed with FAS even when a history of regular gestational alcohol use cannot be confirmed.

In an attempt to formalize diagnostic criteria for FAS and other gestational alcohol-related effects, the Institute of Medicine proposed some additional descriptors that are in common use.³⁰⁰ Partial FAS is applied to a child with some of the characteristic facial features and with growth retardation, neurodevelopmental abnormalities, or other behavioral problems. Alcohol-related birth defects are congenital anomalies other than the characteristic facial features described earlier, for example, cleft palate, which sometimes occurs with regular gestational alcohol use. Alcohol-related neurodevelopmental disorder describes neurodevelopmental abnormalities or other behavioral problems, which sometimes occur with regular gestational alcohol use. Fetal alcohol spectrum disorders (FASDs) is an umbrella term describing the range of effects that can occur in an individual whose mother drank alcohol during pregnancy.^{32,294}

Differential expression of the syndrome may reflect the effects of varying quantities of ethanol ingested at critical periods specific for particular effects. The craniofacial anomalies probably represent teratogenic effects during organogenesis, but some CNS abnormalities and growth retardation may result from adverse effects later in gestation.

There is considerable controversy about what amount of alcohol consumption can cause FASD.^{221,229} Approximately 10% of women consume some alcohol during pregnancy, 2% are frequent users, and 2% binge. Of women who might become pregnant, about 50% drink some alcohol, 13% drink frequently, and 12% binge.⁵² Some researchers believe that the FASD is a result of alcoholism—chronic regular use or frequent bingeing—rather than to low concentrations of gestational ethanol exposure, no matter how little or how infrequent.^{4,115} A high level of consumption would be in the range of 50 to 100 mL of 100% ethanol (four to six “standard” drinks of hard liquor) regularly throughout pregnancy³⁰⁰ or binge drinking (at least five standard drinks per occasion), with a significantly elevated peak blood ethanol concentration.^{3,197} Literature suggests that behavioral abnormalities are associated with the reported consumption of as little as one drink per week.²⁹⁵ In this regard, neither a no-effect amount nor a safe amount of ethanol use in pregnancy has been determined,¹⁴⁹ and therefore the US Surgeon General recommends no alcohol consumption during pregnancy.²³²

The incidence of FAS is 0.5 to 3 per 1000 live births; 4% of women who drink heavily may give birth to children with FAS.^{2,207} This means that several hundred children with FAS and several thousand with fetal alcohol effects will be born each year; thus, ethanol use is considered the leading preventable cause of intellectual disability in this country.³⁰⁰ Although the primary determinant of FAS and its effects is the amount of maternal ethanol consumption, there is some evidence that paternal ethanol exposure may play a contributing role.¹

Ethanol use during pregnancy may lead to an increased incidence of spontaneous abortion, premature deliveries, stillbirths,¹⁹⁸ neonatal ethanol withdrawal,^{28,227} and possibly carcinogenesis.¹⁵⁶ Infants may be irritable or hypertonic and may have problems with habituation and arousal. Long-term behavioral and intellectual effects include decreased IQ, learning disabilities, memory deficits, speech and language disorders, hyperactivity, and dysfunctional behavior in school.^{206,295,301}

Brain autopsies of children with FAS demonstrate malformations of gray and white matter, a failure of certain regions such as the corpus callosum to develop, a failure of certain cells such as the cerebellar astrocytes to migrate, and a tendency for tissue in certain regions to die.⁹⁷ The mechanisms of ethanol-induced teratogenesis are not fully elucidated.^{29,121} Much of the work in animals has focused on the developing nervous system, where ethanol adversely affects nerve cell growth, differentiation, and migration, particularly in areas of the neocortex, hippocampus, sensory nucleus, and cerebellum.^{117,303}

Several mechanisms are potential contributors to the effects of ethanol.¹¹⁴ Ethanol interferes with a number of different

growth factors, which may affect neuronal migration and development.³³¹ In addition, ethanol interferes with the development and function of both serotonin and N-methyl-D-aspartate (NMDA) receptors. Ethanol, or its metabolite acetaldehyde, may also cause cell necrosis directly or through the generation of free radicals and excessive apoptosis.^{64,97,125} In particular, craniofacial abnormalities may be related to apoptosis of neural crest cells through the formation of free radicals, a deficiency of retinoic acid, or the altered expression of homeobox genes that regulate growth and development.³⁰³

One integrative model of ethanol-induced teratogenesis proposes that sociobehavioral risk factors, such as drinking behavior, smoking behavior, low socioeconomic status, and cultural or ethnic influences, create provocative biologic conditions, such as high peak blood ethanol concentrations, circulating tobacco constituents, and undernutrition. These provocative factors exacerbate fetal vulnerability to potential teratogenic mechanisms, such as ethanol-related hypoxia or free radical-induced cell damage.⁵

Opioids

Opioid use in pregnancy remains a significant cause of both maternal and neonatal morbidity. In past month surveys, approximately 0.2% of pregnant women report heroin use, 0.9% report the illicit use of prescription pain relievers, and 0.1% report the use of oxycodone (OxyContin).²⁶⁹ Up to 75,000 babies per year may be exposed to methadone or heroin in utero.²²² Most clinical research regarding opioid toxicity during pregnancy relates to the use of heroin or methadone.

Pregnant opioid users are at increased risk for many medical complications of pregnancy, such as hepatitis, sepsis, endocarditis, sexually transmitted infections, and AIDS, and may be at increased risk for obstetric complications, such as miscarriage, premature delivery, or stillbirth.^{100,113} Some of the obstetric complications may be related to associated risk factors in addition to the opioid use. Maternal opioid use most commonly affects fetal growth.^{100,113,337} There is an increased incidence of low birth weight in babies born to opioid-using mothers compared with control participants, and the effect is greater for heroin than for methadone.

There is extensive clinical experience with methadone maintenance during pregnancy. Compared with untreated heroin use, methadone maintenance during pregnancy is associated with better obstetric care, decreased risk of maternal withdrawal, increased fetal growth, decreased fetal mortality, decreased risk of HIV infection, and increased likelihood that a child will be discharged home with his or her parents.¹⁴⁶ Women who receive low-dose methadone and good prenatal care are at increased risk for pregnancy-related complications but have birth outcomes similar to nonusers.¹⁰⁰ For these reasons, methadone maintenance has become the standard opioid replacement therapy during pregnancy.¹³⁵

Nonetheless, alternatives to methadone are being explored. Just as alternative opioid replacement strategies with buprenorphine have been introduced for opioid users in general, new strategies using buprenorphine in pregnancy are being tested. In one large trial, obstetric outcomes were similar after buprenorphine treatment compared with methadone, although more women in the buprenorphine arm dropped out of the study because they did not feel well during the induction of therapy.^{146,147} One group in Australia is using implantable naltrexone in pregnant patients after opioid detoxification.^{137,138}

The most significant acute neonatal complication of opioid use during pregnancy is the neonatal withdrawal syndrome (NWS), which is characterized by hyperirritability; GI dysfunction; respiratory distress; and vague autonomic symptoms, including yawning, sneezing, mottling, and fever.¹³⁵ Myoclonic jerks or seizures may also signify neurologic irritability. Withdrawing infants are recognizable by their extreme jitteriness despite efforts at consolation; ecchymoses and contusions may be found on the tips of their fingers or toes as a result of trauma from striking the sides of the bassinet. Approximately 50% to 90% of methadone, heroin, buprenorphine, and probably other chronic opioid-exposed newborns show some signs of withdrawal.^{100,146}

Opioid withdrawal symptoms typically occur within one week of birth. Heroin withdrawal usually occurs within the first 24 hours, but methadone and buprenorphine withdrawal usually occur within 2 to 3 days of age. The onset of methadone withdrawal is delayed because methadone has a larger volume of distribution and slower metabolism in the neonate and therefore an increased half-life. The onset and severity of methadone withdrawal may be related to absolute neonatal serum concentration or the rate of decline in concentration.^{83,168} In one study, methadone withdrawal occurred when the plasma concentration fell below 0.06 mg/mL.²⁶²

The onset and severity of symptoms may also be related to which opioid(s) as well as other licit and illicit substances were used; how much was used chronically; how much was used near the time of delivery; the character of the labor; whether analgesics or anesthetics were used; and the maturity, nutrition, and medical condition of the neonate.⁸⁰ Acute neonatal withdrawal symptoms generally last from days to weeks, but as many as 80% of infants have been reported to have recurrence of some symptoms such as restlessness, agitation, tremors, wakefulness, hyperphagia, colic, or vomiting for 3 to 6 months.⁵⁸ In general, the incidence and severity of withdrawal are thought to be greater from methadone than from either heroin or buprenorphine.¹³⁵ When methadone was compared with buprenorphine, buprenorphine-exposed infants

required lower total doses of morphine to control symptoms, had shorter courses of treatment, and had shorter hospitalizations overall.^{146,147}

From 5% to 7% of babies showing signs of withdrawal experience seizures, generally by 10 days after birth.¹²⁷ Seizures may be more likely after methadone withdrawal than after heroin withdrawal. These seizures do not necessarily predispose to idiopathic epilepsy; in one small study, children who had withdrawal seizures were without seizures and had normal neurologic examination findings and psychometric testing at one-year follow-up.⁸⁴

Treatment of withdrawal begins by providing a comforting environment: swaddling or tightly wrapping the infant, minimal handling or stimulation, and demand feeding. More severe symptoms may require pharmacologic therapy. The severity of withdrawal as measured by a standardized scoring scale determines the need for therapy; several scales are in use.^{100,185} In general, babies who are extremely irritable; have feeding difficulties, diarrhea, or significant tremors; or cry continuously are candidates for pharmacologic therapy.¹³⁵

Opioid agonists such as morphine, methadone, tincture of opium, and paregoric; sedative-hypnotic agents such as diazepam and phenobarbital; and clonidine have all been used both individually and in various combinations to treat withdrawal symptoms. Few well-controlled trials have evaluated the relative efficacy of the different interventions or examining long-term effects of therapy.^{234,235} Oral morphine is preferred to treat withdrawal symptoms because it is a short-acting pure opioid agonist, and the formulation has no additives.²⁴⁴ Clonidine and phenobarbital are beneficial as adjunctive therapies.

Opioid agonists may be more effective at preventing withdrawal seizures from heroin or methadone than from phenobarbital or diazepam.^{127,151} However, sedative-hypnotic agents are commonly used by heroin users or adults maintained on methadone, and sedative-hypnotic withdrawal seizures may contribute to the overall neonatal abstinence symptomatology. In this setting, there may be a role for phenobarbital.

Infants of opioid-using mothers have a two to three times increased risk for SIDS compared with control participants.^{152,153} The mechanism may be related to a decreased medullary responsiveness to CO₂, or the effect may be related to some condition of the postnatal environment.¹⁰⁰

Although young children born to opioid users do not seem to have significant differences in behavior compared to control participants, older children have increased learning problems and school dysfunction particularly related to behavior difficulties.³³⁷

Cocaine

Approximately 1% of pregnant women in the United States use cocaine at some time during their pregnancy.²²² The rate may be as high as 15% in certain populations,⁷⁷ and it is estimated that more than 100,000 infants born in the United States each year may be exposed to cocaine in utero.⁵⁶ The consequences of cocaine use during pregnancy have been extensively reviewed.^{131,241,283}

The incidence of abruptio placentae may be significant when related to acute cocaine use.²⁸⁷ Some uncommon perinatal problems include seizures, cerebral infarctions, and intraventricular hemorrhage.^{61,241}

Cocaine use is significantly related to decreases in gestational age, birth weight, length, and head circumference, although these growth parameters generally correct by several years of age.²⁸³ In addition, these growth effects are exacerbated by concomitant alcohol, tobacco, and opioid use.²⁸³ Good prenatal care can mitigate many of these adverse effects of cocaine.^{193,252,337}

Significant congenital malformations were reported among some infants who were exposed to cocaine in utero, specifically genitourinary malformations, cardiovascular malformations, and limb-reduction defects.^{49,104} However, in one large population-based study, there was no increase in the incidence of malformations.²⁰³

Teratogenic effects are observed in animal models of in utero cocaine exposure. Decreased maternal and fetal weight gain and an increased frequency of fetal resorption were demonstrated in rats⁹⁶; sporadic physical anomalies are also observed.⁶³ Teratogenic effects similar to those observed in humans were reported in mice, including bony defects of the skull, cryptorchidism, hydronephrosis, ileal atresia, cardiac defects, limb deformities, and eye abnormalities.^{101,194,195,213} Cocaine caused hemorrhage and edema of the extremities, and, subsequently, limb-reduction defects in rats when administered during midgestation in the postorganogenic period.³²⁴

The perinatal effects of cocaine are probably mediated through a vascular mechanism. Cocaine administration in the pregnant ovine model causes increased uterine vascular resistance, decreased uterine blood flow, increased fetal heart rate and arterial blood pressure, and decreased fetal PO₂ and O₂ content.^{22,333} Similar effects are reported in rats.²³⁷ Fetal hypoxia may cause rupture of fetal blood vessels and infarction in developing organ systems such as the genitourinary system^{60,213,293} or the CNS.^{57,82,325} Hyperthermia or direct effects of cocaine in the fetus may exacerbate these effects.⁴⁰

Limb-reduction defects similar to those attributed to cocaine can be produced after mechanical clamping of the uterine vessels.^{40,326} A developing concept is that after vasospasm and ischemia, reperfusion occurs with the generation of oxygen free radicals and subsequent injury.^{333,334}

Despite the reported malformations and a possible mechanism, neither the human epidemiology nor the effects observed in animal models suggest a specific teratogenic syndrome. The risk of a significant malformation from prenatal cocaine exposure is low, but the effect, if one occurs, may be severe.^{41,89,104}

One of the greatest concerns about prenatal cocaine exposure is the potential adverse effect on the developing child, and this is an intensive area of epidemiologic research. The most common findings in early infancy are lability of behavior and autonomic regulation; decreased alertness and orientation; and abnormal reflexes, tone, and motor maturity; however, many studies show no effect, especially after controlling for confounding variables.^{95,283} For some children, effects may manifest in later infancy as difficulty with information processing and learning. For school-age children, observed cognitive deficits may also be related to the home environment even for children who showed some of the typical neonatal behaviors.^{102,283} Nonetheless, there is evidence of impairment in modulating attention and impulsivity, which makes handling unfamiliar, complex, and stressful tasks more difficult,^{209,283} and these effects are also observed in animal models of prenatal cocaine exposure.^{89,123,182,296}

The mechanism of neurotoxicity has not been specifically elucidated. As described earlier, for many of the maternal and fetal physical defects, cocaine may have direct toxicity or, alternatively, effects may be mediated through hypoxia or oxygen free radicals. Because cocaine interferes with neurotransmitter reuptake, it is likely that cocaine also disrupts normal neural ontogeny by interfering with the trophic functions of neurotransmitters on the developing brain, in particular dysfunction of signal transduction via the dopamine D₁ receptor.^{123,182,199,208} These mechanisms may be more important in the etiology of neurobehavioral effects.

BREASTFEEDING

In the United States, breastfeeding is the recommended method of infant nutrition because it offers nutritional, immunologic, and psychological benefits without additional costs. Many women use prescription and nonprescription xenobiotics while breastfeeding and are concerned about the possible ill effects on their infants of these xenobiotics in the breast milk. This concern extends to the possible exposure of infants to occupational and environmental xenobiotics via breast milk.^{259,278} The response to many of these concerns can be determined by the answer to the following question: Does the risk to an infant from a xenobiotic exposure via breast milk exceed the benefit of being breastfed?¹⁷⁶

Pharmacokinetic factors determine the amount of xenobiotic available for transfer from maternal plasma into breast milk; only free xenobiotic can traverse the mammary alveolar membrane. Most xenobiotics are transported by passive diffusion. A few xenobiotics, such as ethanol and lithium, are transported through aqueous-filled pores. The factors that determine how well a xenobiotic diffuses across the membrane are similar to those for other biologic membranes such as the placenta: MW, lipid solubility, and degree of ionization.

Large-molecular-weight xenobiotics, such as heparin and insulin, do not pass into breast milk. Lipid solubility is important not only for diffusion but also for xenobiotic accumulation in breast milk because breast milk is rich in fat, especially breast milk that is produced in the postcolostral period (~ 3–4 days postpartum). With a pH near 7.0, breast milk is slightly more acidic than plasma. Consequently, xenobiotics that are weak acids in plasma exist largely as ionized molecules and cannot be easily transported into milk. Conversely, xenobiotics that are weak bases exist in plasma largely as nonionized molecules and are available for transport into breast milk. In breast milk, ionization of the weak base xenobiotics occurs, and the xenobiotics are concentrated as a result of ion trapping. In other words, xenobiotics that are weak bases may concentrate in breast milk. Whereas sulfacetamide (pK_a of 5.4, a weak acid) has a concentration in plasma 10 times its concentration in breast milk, sulfanilamide (pK_a of 10.4, a weak base) is found in equal concentrations in both plasma and breast milk.¹⁷⁶

The net effect of these physiologic processes is expressed in the milk-to-plasma (M/P) ratio. Xenobiotics with higher M/P ratios have relatively greater concentrations in breast milk. The M/P ratio does not, however, reflect the absolute concentration of a xenobiotic in the breast milk, and a xenobiotic with a high M/P ratio is not necessarily found at a high concentration in the breast milk. For example, morphine has an M/P ratio of 2.46 (is concentrated in breast milk), but only 0.4% of a maternal dose is excreted into the breast milk.²¹ In general, for most pharmaceuticals, approximately 1% to 2% of the maternally administered dose is presented to the infant in breast milk.¹⁷⁶

The M/P ratio has several limitations. It does not account for differences in xenobiotic concentration that may result from (1) repeat or chronic dosing, (2) breastfeeding at different times relative to maternal xenobiotic dosing, (3) differences in milk production during the day or even during a particular breastfeeding session, (4) the time postpartum (days, weeks, or months) when the measurement is made, and (5) maternal disease.

While being cognizant of the limitations, a spot breast milk xenobiotic concentration or a concentration estimate based

on the M/P ratio allows a simplistic estimation of the quantity of xenobiotic to which an infant is exposed, assuming a constant breast milk concentration:

$$\text{Infant dose} = \text{Breast milk concentration} \times \text{Amount consumed}$$

The effect of this dose on the infant depends on the bioavailability of the xenobiotic in breast milk, the pharmacokinetic parameters that determine xenobiotic concentrations in the infant, and the infant's receptor sensitivity to the xenobiotic. These parameters are often different in neonates than in adults and may lead to xenobiotic accumulation; generally, absorption is greater, but metabolism and clearance are reduced.²⁰ These effects are exaggerated in premature infants.^{247,256} The amount of most xenobiotics delivered to infants in breast milk is usually adequately metabolized and eliminated.¹⁷⁶

Many of the above considerations are theoretical, and the number of specifically contraindicated xenobiotics is quite small.¹⁴ Published guidelines on the advisability of breastfeeding during periods of maternal therapy are generally based on the expected effects of full doses in the infant or on case reports of adverse occurrences. Interestingly, when the reports of adverse effects were reviewed, 37% of cases were in infants younger than 2 weeks old, 63% were in infants younger than 1 month old, and 78% were in infants younger than 2 months old; 18% were in infants 2 to 6 months old; and only 4% were in infants older than 6 months.¹⁶ It seems, therefore, that adverse effects are most likely to be observed in the first few weeks of life, when an infant's metabolic capacity is significantly less than that of an older infant, child, or adult.^{9,79}

For most xenobiotics, a risk-to-benefit analysis must be made. For example, lithium is transferred in breast milk and may lead to measurable, although subtherapeutic, serum concentrations in a breastfed infant. Although the effects of such exposure to lithium are unknown, many practitioners believe that the benefit of treating a mother's bipolar illness outweighs the potential risk to the infant.^{176,277} There may also be a small increased risk of carcinogenicity associated with exposure to some environmental xenobiotics through breast milk.²⁵⁹

Similarly, the breastfed infant of a woman who smokes is exposed to nicotine and other tobacco constituents, both by inhalation and via breast milk. Although this child may be at increased risk for respiratory illness as a result of exposure to tobacco smoke, some of the risk may be reduced by breastfeeding.^{14,254}

In most cases, women do not need to stop breastfeeding while using pharmaceuticals, such as most common antibiotics. However, "compatibility" with breastfeeding is generally based on a lack of reported adverse effects, which may reflect limited clinical experience with a particular xenobiotic in breastfeeding patients. Therefore, in the setting of limited information, exposure to a xenobiotic through breast milk should be regarded as a small potential risk, and the infant should receive appropriate medical follow-up. Not all "compatible" medications are safe in all situations. For instance, phenobarbital can produce CNS depression in an infant if the mother's serum concentration is in the high therapeutic or supratherapeutic range, which often occurs while dosage adjustments are being made. Such a concentration may or may not produce CNS depression in the mother. Nalidixic acid, nitrofurantoin, sulfapyridine, and sulfisoxazole, although generally safe, can cause hemolysis in a breastfed infant with glucose-6-phosphate dehydrogenase deficiency.

When women use substances postpartum, there is delivery of some xenobiotic to the infant via breast milk, and there are rare cases reports of infants experiencing adverse effects.⁵⁹ Because of these possible direct effects on the baby, as well as the detrimental effects on the physical and emotional health of the mother and on the caregiving environment, the use of substances such as cocaine, methamphetamine, and heroin during the breastfeeding period is discouraged, and women actively using substances are discouraged from breastfeeding.¹⁴ However, women who are or have been abstinent from substance use and are participating in a treatment program are generally encouraged to breastfeed their infants.^{6,176}

Although ethanol is not specifically contraindicated for breastfeeding mothers, decreased milk production and adverse effects in infants are noted with maternal consumption of large amounts of ethanol.

Questions sometimes arise regarding possible lead exposure during breastfeeding. Lead crosses into breast milk from blood and is the most likely source of lead exposure for most breastfeeding infants.¹⁸⁹ Approximately 1% of US women between the ages of 15 and 49 years have blood lead concentrations greater than 5 µg/dL.⁹⁴ Some estimates suggest that breast milk concentrations are less than 3% of the maternal blood lead; therefore, if the maternal lead concentration is 5 µg/dL, then the amount of lead delivered to the infant could be 1.5 µg/L of breast milk.^{118,164} This represents a relatively small exposure. In a sample of breastfed babies from one US city, the mean infant lead concentration was less than 3 µg/dL, the highest concentration was 8 µg/dL, and only 7.8% of values were greater than 5 µg/dL.¹⁸⁹ The current consensus is that the benefits of breastfeeding outweigh the relatively small exposure to lead in breast milk.³²⁹ Blood lead screening for most women is not recommended.

There are, however, some subpopulations of pregnant women at increased risk of elevated environmental lead exposure for whom blood lead screening is recommended. Risk factors for significant lead exposure in pregnant women include recent immigration, pica practices, occupational exposure, poor nutritional status, culturally specific practices such as the use of traditional remedies or imported cosmetics, and the use of traditional lead-glazed pottery for cooking and storing as well as those involved with renovation or remodeling in older homes.⁹⁴

All women should have an assessment of risk for environmental lead exposure. Women at increased risk should have blood lead screening. When possible, pregnant and postpartum women with blood lead concentrations of 5 µg/dL or higher should be removed from occupational or environmental lead sources and discouraged from practices or activities that result in increased exposure.⁹⁴ In addition, some evidence suggests that dietary supplementation of calcium can reduce the mobilization of lead in postpartum women.¹²⁶ In cases of elevated maternal lead concentrations, decisions regarding breastfeeding should be made on an individual basis.

In 2007, after the death of a breastfeeding 13 day-old infant whose mother was using codeine, the US FDA issued a public health advisory regarding the use of codeine by breastfeeding women.³¹⁵ In the initial case, the mother was found to be compound heterozygous for a CYP2D6*2A allele and a CYP2D6*2x2 gene duplication and therefore an “ultrametabolizer” of codeine.¹⁵⁹ In other words, codeine was metabolized to morphine at an exaggerated rate, and the infant ingested a high dose of morphine via the breast milk. The ultrametabolizer phenotype is present in up to 10% of whites and up to 30% of Ethiopians, North Africans, and Saudi Arabians.³¹⁵ In addition, both the mother and the infant were homozygous for the UGT2B7*2 allele, which leads to elevated concentrations of morphine-6-glucuronide, an active metabolite.

Another decreased-function gene variant of ABCB1 may also have a role in this codeine toxicity. ABCB1 codes for a P-glycoprotein involved in transporting morphine out of the CNS. Decreased gene function would lead to increased accumulation of morphine in the CNS and potentially increased toxicity.²⁹⁰

Decisions on breastfeeding should be made with the informed involvement of the woman; her physicians; and when necessary, a consultant with special expertise in this field. Guidelines are available from several sources.^{45,176}

TOXICOLOGIC PROBLEMS IN NEONATES

Physiologic differences between adults and newborn infants affect xenobiotic absorption, distribution, and metabolism.^{20,154,321} Appropriate administration of xenobiotics to newborn infants therefore requires an understanding of the appropriate developmental state for medication dosing and pharmacokinetics. Even so, approximately 8% of all medication doses administered in neonatal intensive care units (NICUs) may be up to 10 times greater or lesser than the dose ordered,⁶⁷ and as many as 30% of newborns in NICUs may sustain adverse drug effects, some of which may be life threatening or fatal.²¹ Pharmacokinetic differences between adults and newborns may account for some cases of unanticipated xenobiotic toxicity that occur in newborn infants.

Gastrointestinal absorption of xenobiotics in neonates is generally slower than in adults.^{20,154,321} This delay may be related to decreased gastric acid secretion, decreased gastric emptying and transit time, and decreased pancreatic enzyme activity. The GI environment of newborns and young infants may allow the growth of *Clostridium botulinum* and the subsequent development of infantile botulism (Chap. 41). Infantile botulism has been reported in infants several weeks of age.^{139,308}

Although it is uncommon, cutaneous absorption of xenobiotics may be a route of toxic exposure in a newborn.^{92,268} Aniline dyes used for marking diapers are absorbed, causing methemoglobinemia,²⁶⁸ and contaminated diapers were responsible for one epidemic of mercury poisoning.²⁵ The absorption of hexachlorophene antiseptic wash has led to neurotoxicity with marked vacuolization of myelin seen microscopically.^{172,204,288} The dermal application of antiseptic ethanol has caused hemorrhagic necrosis of the skin of some premature infants. Iodine antiseptics have led to hypothyroidism in mature newborns.⁵³ An increased potential for absorption and toxicity has followed the application of corticosteroids^{109,266} and boric acid⁹⁰ to the skin of children with cutaneous disorders.

Other routes of exposure have led to clinical poisoning. Several children aspirated talcum powder and died.^{46,220} Inhalation of mercury from incubator thermometers may be a potential risk.¹³ One child died after the ophthalmic instillation of cyclopentolate hydrochloride.²⁷

Because of differences in total body water and fat compared with adults, the distribution of absorbed xenobiotics may differ in neonates.^{20,154,321} Water represents 80% of body weight in a full-term baby compared with 60% in an adult. Approximately 20% of a term baby's body weight is fat compared with only 3% in a premature baby. The increased volume of water means that the volume of distribution for some water-soluble xenobiotics, such as theophylline and phenobarbital, is increased.

Protein binding of xenobiotics is reduced in newborns compared with adults: the serum concentration of proteins is lower, there are fewer receptor sites that become saturated at lower xenobiotic concentrations, and binding sites have decreased binding affinity.^{20,154,321} Protein binding has potential relevance with respect to bilirubin, an endogenous metabolite that at very high concentrations can cause kernicterus; bilirubin competes with exogenously administered xenobiotics for protein binding sites. In vitro, certain xenobiotics, such as sulfonamides and ceftriaxone, displace bilirubin from protein receptor sites, which might increase the risk of kernicterus, although this has not been clinically demonstrated.

Conversely, bilirubin may itself displace other xenobiotics, such as phenobarbital or phenytoin, leading to increased plasma xenobiotic concentrations.

Newborn infants have decreased hepatic metabolic capacity compared with adults, which may lead to xenobiotic toxicity.^{20,154} For example, caffeine, used in the treatment of neonatal apnea, has an extremely prolonged half-life in newborns because CYP1A2 has only 5% of the normal adult activity.²⁰ Except for CYP1A2, most of the CYP isoenzymes reach approximately 25% of adult activity in newborns by about 1 month of age.

Two syndromes related to immature metabolic function are described. The “gasping baby syndrome,” characterized by gasping respirations, metabolic acidosis, hypotension, CNS depression, convulsions, kidney failure, and occasionally death, is attributed to high concentrations of benzyl alcohol and benzoic acid in the plasma of affected infants.^{12,48,110} Benzyl alcohol, a bacteriostatic, was added to IV flush solutions and accumulated in newborns after repetitive doses. The high concentrations of benzoic acid could not be further metabolized to hippuric acid by the immature liver. Immature glucuronidation in neonates is responsible for the “gray-baby syndrome” after high doses of chloramphenicol (Chaps. 32, 55, and 57).¹³⁰

The umbilical vessels are a common site of vascular access in sick neonates. Because blood drains into the portal vein, it is possible that IV medications experience a “first-pass” effect, although whether this route of xenobiotic administration affects metabolism or clearance has not been well studied. Most functions of the kidney, including glomerular filtration rate (GFR) and tubular secretion, are relatively immature at birth²⁰; the GFR of a newborn is approximately 30% of that of an adult. Xenobiotics such as aminoglycosides and digoxin are excreted unchanged by the kidney and therefore depend on glomerular filtration for clearance. Dosing of these xenobiotics in a newborn must account for these differences.

An interesting association has been made periodically over the years between the use of erythromycin, particularly in the first 2 weeks of life, and idiopathic hypertrophic pyloric stenosis.^{66,132,196,271,297} Although erythromycin is known to interact with motilin receptors in the antrum of the stomach, no specific etiology has been defined.¹²⁴

Very little information is available to guide clinicians in the management of xenobiotic poisoning in newborn infants. Cutaneous absorption is probably already complete by the time toxicity is noted, although further exposure may be prevented. GI decontamination is not generally performed in neonates, and neonates may be at increased risk of fluid, electrolyte, and thermoregulatory problems after gastric lavage or the use of cathartic agents. Multiple-dose activated charcoal was used in a 1.4-kg, 2 week-old premature infant to treat iatrogenic theophylline toxicity.²⁸⁴ Hemodialysis, hemoperfusion, and exchange transfusion can be used in neonates to treat xenobiotic toxicity (Chaps. 10 and 32).

SUMMARY

- Human embryos and fetuses are exposed to xenobiotics through the placenta of the pregnant woman; the neonates are exposed to xenobiotics via breast milk.
- Xenobiotic effects on developing humans include both congenital malformations as well as neurobehavioral abnormalities, which may manifest later in a child’s or adult’s life.
- The use of xenobiotics in a pregnant or breastfeeding woman is a complex area of medical practice and presents clinicians with potentially difficult management decisions regarding the benefit of therapy to the mother and the risk to the mother or fetus of xenobiotic exposure. In general, the goal is to optimize benefit to the mother while minimizing the risk to the fetus. In almost all cases, the primary approach is to fully and appropriately treat the mother.
- Appropriate management of many of the potential problems is facilitated by the coordinated efforts of obstetricians, perinatologists, neonatologists, pediatricians, and toxicologists.

32 PEDIATRIC PRINCIPLES

Jeffrey S. Fine

Phone calls to poison centers regarding childhood exposures to xenobiotics are more frequent than those regarding any other age group. Because of this and the frequent role of poisoning as a cause of pediatric injury, pediatricians have been active for many years in helping to establish and promote the study of medical toxicology, as well as in establishing and supporting the use of regional poison centers. Although the basic approaches to the medical management of toxicologic problems outlined in Chaps. 3 and 4 are generally applicable to both children and adults, issues such as child abuse by poisoning are of particular concern. This chapter provides a perspective on the application of generally accepted toxicologic principles for children.

EPIDEMIOLOGY

To analyze the problem of pediatric poisoning, it is necessary to understand the magnitude of the problem. When assessing the impact of a particular type of injury such as poisoning, epidemiologists examine multiple parameters, such as exposure, morbidity, mortality, and cost, to measure the effect of the injury; however, these parameters are difficult to measure accurately. An important source for information on the extent and effects of poisoning exposures in the United States is the American Association of Poison Control Centers (AAPCC). Every year, the AAPCC compiles standardized data collected from poison centers throughout the United States; the 2012 annual review includes information submitted by 57 poison centers. In the following discussion, comments on AAPCC data refer to cumulative information from the previous five published reports covering the years 2007 to 2011 ([Chap. 136](#)).

Each year, the AAPCC reports approximately 1.2 million potentially toxic exposures in children and adolescents from birth to 19 years, which account for 66% of all reported exposures. In fact, children younger than age 6 years account for 53% of all reported exposures. Of the reported exposures in children and adolescents, children younger than age 6 years account for 79%, children between 6 and 12 years of age account for 10%, and adolescents between 13 and 19 years of age account for 11%. Girls represent 47% of the reported poisoning exposures in young children and 54% of the reported exposures among adolescents.

Among the AAPCC reported xenobiotic exposures in children younger than age 6 years, 99% are labeled unintentional. In contrast, only 44% of the reported adolescent exposures are unintentional; 50% of exposures in adolescents are labeled intentional, mostly resulting from substance use or suicide attempts. The high frequency of intentional poisoning in adolescents has been reported by others.^{34,183,184} The remaining 6% of adolescent exposures include adverse drug events and other miscellaneous or unknown causes. Differences in the reasons for exposure between young children and adolescents account for differences in the outcomes of these exposures.

Approximately 125,000 xenobiotic exposures each year are classified by the AAPCC as therapeutic errors, accounting for approximately 6% of exposures in children younger than 6 years of age, 24% in children 6 to 12 years of age, and 11% in adolescents. An additional 4700 exposures each year are classified as adverse drug reactions, which account for approximately 0.4% of exposures in children younger than 6 years of age, 2% in children 6 to 12 years of age, and 3% in adolescents.

[Table 32–1](#) shows the leading causes of reported exposures in children and adolescents. According to the AAPCC, approximately 54% of childhood exposures are to xenobiotics that are commonly found around the house, such as cleaning products, cosmetics, plants, hydrocarbons, and insecticides; approximately 46% are to pharmaceuticals. In older children and adolescents, approximately 49% of exposures are to nonpharmaceutical xenobiotics, and approximately 51% are to pharmaceuticals. Most hospitalizations and deaths in both groups are caused by pharmaceuticals.

TABLE 32–1. Average Annual Xenobiotic Exposures Reported to the American Association of Poison Control Centers (2007–2011)^{a,b}

<i>Age Younger Than 6 Years</i>	
<i>Category</i>	<i>Number of Exposures</i>
Cosmetics and personal care products	166,950
Cleaning substances	115,268
Analgesics	110,325
Topical preparations	84,882
Vitamins	47,080
Cough and cold preparations	42,426
Insecticides, pesticides, and rodenticides	40,793
Antihistamines	39,926
Plants	36,789
Gastrointestinal preparation	33,697
<i>Ages 6–19 Years</i>	
<i>Category</i>	<i>Number of Exposures</i>
Analgesics	32,953
Cosmetics and personal care products	16,011
Cough and cold preparations	13,662
Cleaning substances	13,483
Bites and envenomations	13,196
Antihistamines	11,142
Sedative–hypnotics	11,126
Stimulants and street drugs	10,295
Antidepressants	9014
Pesticides	7448

^aSee Chap. 136 for references and discussion. ^bDoes not include the American Association of Poison Control Centers' category "foreign bodies."

Table 32–1 lists the most common reported exposures, but not all of these exposures lead to serious morbidity and mortality (Table 32–2). For example, children frequently ingest cosmetic products, so the number of reported exposures is large, but most cosmetics manufactured in the United States are nontoxic. Clinically significant poisoning is unusual in children younger than age 6 months but may result from the inadvertent administration of an incorrect drug or drug dose by a parent,^{60,123} intentional administration of a drug by a parent or sibling,^{43,74} or passive exposure (eg, to the smoke of “crack” cocaine or phencyclidine).^{16,73,124,158,192} Any poisoning in a child younger than one year of age should be carefully evaluated for possible child abuse or neglect (see later discussion).⁷⁴

TABLE 32–2. Xenobiotics Responsible for Significant Pediatric Poisoning Morbidity and Mortality

Category	Younger Than 6 Years Old						13–19 Years Old	
	Reported Major Effects ^a		Reported Deaths ^b		Reported Deaths 2007–2011 ^b		Reported Deaths 2007–2011 ^b

^aData from Litovitz T, Manoguerra A: Comparison of pediatric poisoning hazards: an analysis of 3.8 million exposure incidents. *Pediatrics*. 1992;89:999–1106. ^bData from American Association of Poison Control Centers (AAPCC), 2007 to 2011. ^cMajor effect is defined as life-threatening signs and symptoms, or significant residual disability or disfigurement. ^dThe AAPCC does not report specific outcomes, other than death, by age, for individual xenobiotics; consequently, the number of major effects cannot be calculated from annual reports.

Several typical characteristics associated with ingestions by toddlers differentiate them from ingestions by adolescents or adults: (1) they are without suicidal intent; (2) there is usually only one xenobiotic involved; (3) the xenobiotics are usually nontoxic; (4) the amount is usually small; and (5) toddlers usually present for evaluation relatively soon after the ingestion is discovered, generally within 1 to 2 hours. As many as 30% of children who experience one ingestion will experience a repeat ingestion; adolescents may be particularly prone to recidivism.^{61,81} Children who ingest poisons may also be at a greater risk for other types of injuries.^{14,51}

The peak age for childhood poisoning is between 1 and 3 years.²⁹ Unintentional ingestion is unusual after age 5 years, although when it occurs, it can sometimes be the result of mistaken consumption of a xenobiotic from a mislabeled container.²⁶ Between the ages of 5 and 9 years, poisoning may result from intrafamilial stress or suicidal intent. After age 9 years and through adolescence, overdose or poisoning frequently results from either suicidal gestures and attempts or from the adverse effects of alcohol or substance use. Unintentional poisonings are largely preventable (Chap. 136).

Because many children are exposed to nontoxic xenobiotics or to only small amounts of potentially toxic xenobiotics, the proportion of children and adolescents who experience significant morbidity is small (Table 32–3). However, because there are millions of such exposures each year, the number of children and adolescents who experience at least moderate effects is large.

TABLE 32–3. Outcome of Reported Pediatric Xenobiotic Exposures (2007–2011)^a

Age (years)	Effects (% of Reported Exposures) ^{b,c}			
	Minor or None	Moderate	Major	Death
0–5	99	0.86	0.07	0.004
6–12	97	3	0.15	0.007
13–19	86	13	1.3	0.05
All children and adolescents 0–19	98	2	0.20	0.009

^aSee Chapter 136 for references and discussion. ^bApproximate percentage. ^cMinor is minimal signs and symptoms, often not requiring therapy or had no follow-up; moderate is more pronounced, prolonged, or systemic signs and symptoms, often requiring therapy; and major is life-threatening signs and symptoms.

Another source of data related to poisoning morbidity is the National Injury Surveillance database maintained by the US Centers for Disease Control and Prevention (CDC), which provides information on emergency department (ED) visits and hospitalizations.³⁰ For the period 2001 to 2011, the CDC estimates approximately 59,000 ED visits (246 per 100,000) and 3900 hospitalizations (~7%) per year for children 0 to 5 years who are exposed to a xenobiotic. Children 6 to 12 years account for approximately 11,000 ED visits (40 per 100,000) and 1000 hospitalizations (9%) per year, and adolescents 13 to 19 years old account for approximately 100,000 ED visits (349 per 100,000) and 21,000 hospitalizations (21%) per year. Overall, approximately 80% of the patients hospitalized are adolescents, and approximately 75% of those cases are the result of intentional poisonings.

These numbers are consistent with estimates of 100,000 to 170,000 ED visits for poisoning and overdose per year, or approximately 300 to 840 visits per 100,000 for children younger than 5 years of age and 290 to 360 per 100,000 visits for adolescents. Hospitalization rates are 10% to 20%.^{28,29,52,59,114,180}

As mentioned, adolescents are more frequently hospitalized than children after exposure to xenobiotics.⁶¹ This may be a result of the need for either medical management or psychiatric hospitalization. The peak age for hospitalizing young children exposed to xenobiotics is between 1 and 3 years, reflecting the peak age of exposure. Whereas among hospitalized children younger than age 2 years, exposure to nonpharmaceutical xenobiotics is more common, children older than age 2 years and adolescents are more commonly exposed to pharmaceuticals.^{52,61,183}

Although the AAPCC reports overall outcome related to age, it does not generally stratify outcome of exposure to individual xenobiotics by age. In a multiyear review published in 1992, the AAPCC reported the xenobiotics that caused the greatest number of major and fatal effects in children younger than 6 years old.¹⁰⁵ Table 32–2 lists the xenobiotics causing significant morbidity and mortality. Other reports of hospitalized patients include a similar distribution of xenobiotics that cause significant morbidity.^{8,31,45,197} However, in rural areas of many developing countries, kerosene and pesticides are the leading causes of xenobiotic-related hospitalizations, and the spectrum of pharmaceutical exposures is often different^{1,2,110,122,128} (Chap. 137).

Poisoning accounts for approximately 2% of childhood and 7% of adolescent injury-related deaths in the United States.³⁰ Based on information from death certificates filed in state vital statistics offices as well as demographic information provided by funeral directors, the CDC reports 1123 poisoning deaths in children younger than 6 years of age from 1999 to 2010 for an average of about 94 per year. These deaths represent approximately 10% of the reported poisoning fatalities for all children and adolescents for those years and a 79% decrease from the 456 deaths reported by the CDC in 1959.²⁹ There may be several factors responsible for this decrease. Some of the difference may be related to improved poisoning prevention strategies such as child-resistant closures or to improved medical care. In addition, some industrial or pharmaceutical products that were previously found around the home may have been replaced with less toxic products or been reformulated at safer concentrations. It is also possible that there may have been a decrease in reporting (Chap. 136).

Forty-seven percent of the AAPCC-reported childhood fatalities result from unintentional ingestions; 20% are from environmental exposures, mostly carbon monoxide poisoning; 12% are caused by therapeutic errors and adverse reactions; and 10% are malicious. The remaining 11% have miscellaneous causes or are unknown. In contrast, 50% of AAPCC-reported adolescent fatalities are the result of suicide, and 30% follow abuse or misuse of substances; only 2% are related to environmental exposures, and only 2% are caused by medication errors and adverse reactions; the remaining 16% have miscellaneous or unknown causes.

Although the AAPCC data provide a remarkable amount of epidemiologic information, there are questions about the accuracy of the data.^{71,72,190} For example, as mentioned earlier, whereas the CDC reported 1123 poisoning-related deaths in children younger than 6 years of age from 1999 to 2010, the AAPCC reported 409 for those same years based on voluntary calls. Some of the differences may be related to methods of ascertainment. Nonetheless, there is recognition that many significant poisonings are not reported to poison centers. Physicians managing “common” toxicologic problems may

not feel the need for the assistance of a local or regional poison center and may not feel compelled to participate in the reporting process. Therapeutic misadventures may also go unreported. In Rhode Island, only 45 of 369 poisoning deaths were reported to the regional poison center¹⁰³ (Chap. 136).

The most notable difference between the xenobiotics listed in Table 32–2 and studies from the 1960s and 1970s is that salicylates are no longer a leading cause of reported poisoning morbidity and mortality.^{37,42} This change may be related to federal regulations requiring child-resistant closures as well as to the decreased use of aspirin for use in children after a now unproven association between Reye syndrome and aspirin was reported (Chap. 39).^{19,36,79,125,144}

There are some significant etiologic differences between children and adolescents (Table 32–1), particularly with regard to the lethality of xenobiotics. For 2007 to 2011, the xenobiotics causing the greatest number of childhood deaths were analgesics, carbon monoxide, cleaning agents and chemicals, and antihistamines and cough and cold preparations, which together account for 51% of all reported poisoning deaths. The xenobiotics causing the greatest number of adolescent deaths were analgesics, stimulants and street drugs, and antidepressants, which together account for 66% of reported poisoning deaths.

With respect to AAPCC-reported analgesic-related deaths, there are significant differences between children and adolescents for this population of exposed individuals. For children younger than 6 years, opioids accounted for 94% of the analgesic-related deaths (methadone, 52%; oxycodone or hydrocodone, 26%; fentanyl, 10%; and morphine, 10%). The high frequency of childhood exposures to these xenobiotics has been identified as a significant consequence of both the therapeutic and illicit use of prescription opioid analgesics.¹¹ These fatalities were related to unintentional exposures in 48% of the children, malicious exposures or intentional misuse in 23%, and therapeutic errors in 6%; the reasons in the rest of the cases were unknown.

In adolescents, opioids accounted for 55% of the analgesic-related deaths (methadone, 22%; oxycodone or hydrocodone, 16%), and acetaminophen (APAP)-opioid combination products accounted for 13% of the deaths. Forty-one percent of the fatalities were the result of abuse or misuse, and 47% were suicides.

Hydrocarbon-related fatalities occur in both children and adolescents; whereas the hydrocarbon deaths of young children generally result from unintentional aspiration after ingestion, almost all of the hydrocarbon-related deaths in adolescents are related to inhalational abuse of hydrocarbons such as trichloroethanes or chlorofluorocarbons.

Poisoning also has an economic cost. Charges for hospitalized patients range from \$2000 to \$10,000, depending on the length of stay and outcome.^{89,176,197} In a large-scale economic analysis of the cost of injury in the United States in 1985, the estimated average lifetime cost was \$495 per child and \$10,839 per adolescent or young adult injured or killed by poisoning for a total lifetime cost of approximately \$140 million for children and \$1.5 billion for adolescents and young adults.¹³⁷ According to the CDC, for 2005, the average combined medical and work loss cost for children and adolescents treated and released from the ED after an unintentional injury is approximately \$714 and approximately \$1390 after an intentional injury for a total cost of approximately \$88 million. The average cost for a hospitalized patient is approximately \$9000 for a total cost of approximately \$358 million. For fatal injuries, the average medical cost is approximately \$4800, but the average work loss cost is \$1.5 million for a total cost of \$1.5 billion.³⁰

BEHAVIORAL, ENVIRONMENTAL, AND PHYSICAL ISSUES

An oversimplification of the etiology of childhood poisonings would be the formulation that unobserved toddlers exploring their environment inadvertently ingest xenobiotics. However, this approach ignores the complex interplay of factors that may contribute to some ingestions in children.

One approach to understanding injury causation that can be applied to poisoning uses an infectious diseaselike model.⁷⁰ According to this model, there are three interacting factors: host, agent, and environment. These factors interact during three phases: preinjury, injury, and postinjury. The factors themselves contribute to the likelihood, nature, magnitude of, and host response to an injury.

During the preinjury phase, there is an interaction of the host, agent, and environment. Under the proper circumstances, an injury may occur. Modification of these factors may help to prevent an injury. For example, if a 2 year-old child finds two pills on a bedside table, there is a fair chance the child will ingest the tablets. However, storing the pills out of reach of the child can prevent the ingestion.

The injury phase covers both the ingestion and the initial pathophysiologic host response. Again, particular factors determine the nature and extent of injury. Continuing the example, if the two pills are 325-mg APAP tablets, the ingestion will not lead to injury. However, if the pills are 0.2-mg clonidine tablets, there is a high likelihood of toxicity.

The postinjury phase is concerned both with the ongoing host response and the medical management of the patient who has been poisoned. In this phase, it would be determined whether the 2 year-old child with a clonidine ingestion manifests signs of toxicity, such as coma or hypotension; whether the child requires treatment with activated charcoal (AC), intravenous (IV) fluid, or naloxone; and whether the child requires hospital admission.

This paradigm is only a model; in reality, it is often difficult to examine any individual factor independently, and the

relative contributions of these factors are not well defined. Nonetheless, consideration of the individual factors of host, agent, and environment allows us to focus on several relevant aspects of poisoning in children.

Childhood and adolescence are times of tremendous growth and development.²⁰³ Some of these physical and social changes place children and teenagers at increased risk for poisonings. By 7 months of age, an infant sitting up can pivot to grab an object; by 9 to 10 months of age, most infants can creep and crawl; by 15 months of age, most toddlers are walking quite competently and eagerly exploring. Between 9 and 12 months of age, a skillful pincer grasp with the thumb and forefinger develops that allows the child to pick up small objects. Throughout this period, one of the child's primary sensory experiences is sucking on or gumming objects that are placed in the mouth. Thus, the combination of three developmental skills—the ability to move around the home and go beyond the immediate view of a guardian, the ability to pick up and manipulate small objects, and the tendency of children to put things in their mouths—places them at risk for poisoning.

As children develop socially, they desire to become more similar to their parents, and they tend to imitate behaviors, such as taking medicine or using mouthwash. Children are taught that medicine is good for them when they are sick. Many children's medicines are sweetened and flavored to make them more palatable, and many parents inappropriately encourage their children to take medicines by telling them "it tastes like candy." Children have been observed "making tea" from plants or "making pizza" with mushrooms from the yard.²⁶

As children become more mobile, agile, and curious, xenobiotics that were previously outside their reach become accessible even when stored in some difficult-to-reach places. Some evidence suggests that parents underestimate the developmental skills of their children.⁵¹ The meaning of the term unintentional with respect to childhood poisoning should also be reconsidered—a toddler quite purposefully intends to get to a pill and eat it, but the child does not intend to injure him- or herself.

Some of the reasons why a child wants to ingest a pill are because it is there, it looks and maybe tastes like candy or food, or the child is mimicking the behavior of a parent who ingests medicines or vitamins to cure illness and improve health. However, these reasons may not be sufficient to explain why xenobiotic exposures occur. Another aspect of poisoning that must be considered is the interaction between the child's temperament and the social environment.

Many authors have tried to identify psychosocial predictors for childhood poisoning in general and for repeat poisoning in particular.^{22,53,83,169,185} As many as 30% of children repeatedly ingest xenobiotics, frequently the same xenobiotic. Certain risk factors have been identified for single and repeat episodes of childhood poisoning, such as hyperactivity, impulsive risk-taking behavior, rebelliousness, and negativistic attitude. Other factors seem to be associated more with the quality of supervision by parents or guardians, who themselves are experiencing medical illnesses, depression, or social isolation.¹⁸⁵ Finally, a stressful environment or a major social problem may also contribute.^{166,170} It is not difficult to imagine a situation of a parent who is depressed, uses antidepressant medication that is kept at the bedside, and cannot give adequate attention to a demanding child. In a bid for attention or as an expression of anger or frustration, the child ingests some of the parent's medication.

With regard to the agent, a number of issues affect the preinjury and injury phases, and modification of any one of the interacting factors of host, agent, or environment may potentially prevent or reduce the severity of injury. When household products of lower toxicity are available around the house, the likelihood of injury is reduced if one of these products is ingested. For example, less toxic rodenticides such as warfarin have replaced more toxic ones such as thallium or sodium monofluoroacetate, and relatively nontoxic paradichlorobenzene mothballs have largely replaced the relatively more toxic camphor-containing mothballs.

It may also be possible to reduce the likelihood of ingestion by making a xenobiotic unpalatable. Denatonium benzoate is an aversive, bitter xenobiotic that is added to some liquids such as windshield washer fluid and antifreeze to prevent unintentional poisoning.⁸⁰ However, some trials show that whereas older children may respond negatively to these xenobiotics with the first taste, younger children may ingest 1 to 2 teaspoonfuls before being deterred by the bitter flavor.^{20,165} This is an important consideration because even a small amount of a xenobiotic such as methanol can be toxic (see later discussion). The actual usefulness of denatonium benzoate in poison prevention is largely unstudied.¹⁴⁵

The problem of unintentional ingestions is compounded by poison "look-alikes," that is, xenobiotics that resemble candy or food products.⁵⁴ Some common examples are ferrous sulfate tablets and vitamins that look like common candies and fuel oils that come in cans resembling soft drink containers. Many shampoos and dishwashing detergents are given lemon or strawberry scents and have pictures of fruits on the labels. Children are not always able to distinguish poison "look-alikes" from real candies, fruits, and sodas, and they may be attracted to bright colors, pleasant smells, and appealing packages. Eliminating these "look-alikes" might prevent some unintentional ingestions.

Probably the most significant changes have occurred in the physical characteristics with regard to packaging and dispensing of pharmaceuticals and some other xenobiotics with child-resistant closures mandated by the Poison Prevention Packaging Act of 1972 ([Chap. 1](#)). This legislation is credited with causing a significant reduction in morbidity and mortality caused by poisoning from aspirin and other regulated products, although this analysis has been challenged.^{36,143,187} Child-resistant closures have also been credited with reducing the number of toxic exposures to kerosene.⁹⁷

Nonetheless, problems with child-resistant closures include the dispensing of pharmaceuticals in nonresistant containers, not properly closing child-resistant containers, and leaving pharmaceuticals out of the child-resistant container.^{28,168} Seventy percent of potentially toxic pharmaceuticals may be in non-child-resistant or in improperly functioning child-resistant containers. Several studies have identified poor functioning of the closures when there is sticky liquid or pill residue around the top or in the screw threads of the child-resistant container.^{81,89,196}

Although child-resistant containers are a significant deterrent to unintentional ingestions in toddlers, they are not completely effective, and even without the problems noted, some children can open them. A false sense of security associated with these closures may lead some parents to be less compulsive regarding safe storage of the containers. A double barrier, such as a unit-dose dispenser within a child-resistant container or a blister pack, has been recommended for a few pharmaceuticals associated with a large number of significant poisonings such as iron and antidepressants.⁸⁹

In fact, in 1997, the Food and Drug Administration (FDA) issued a regulation to package products with 30 mg or more of elemental iron per tablet in unit-dose packages such as blister packs.³⁰ The intent of this regulation was to reduce the likelihood of iron poisoning in children. Even before this regulation was instituted, the number of fatal childhood iron ingestions had declined significantly; therefore, it is not known how much if any of the decrease is related to the mandated packaging changes. In any case, the rule was overturned in 2003, when it was determined that the FDA did not have the statutory authority to regulate a drug for the purpose of poison prevention.¹¹ As yet there is no evidence of a resurgence of iron-related fatalities.

A discussion of containers and storage naturally leads to a consideration of the third factor in the injury-causation model discussed earlier, the environment, which is particularly important in the preinjury and the injury phases. Approximately 80% of childhood pharmaceutical ingestions occur at home; the remainder occurs at the homes of grandparents, other relatives, and friends. At home, the medicine usually belongs either to the child or to a parent, although a significant number of medications, both at home and away from home, belong to a grandparent.^{81,104} Grandparents, other relatives, and family friends without children at home may not obtain or retain medications in child-resistant containers and may not be as attentive to safe storage practices. Poison prevention education directed to these groups may be particularly helpful.¹¹⁷

Medications are frequently kept in the kitchen or bedroom while they are being used.^{81,196} In the kitchen, medications are stored in the refrigerator, on the table, or on the counter; in the bedroom, medications are left on a dresser or bedside table. A mother's or grandmother's purse is another location where medications are commonly found. Interestingly, there are no significant differences in the storage practices in the homes of children who ingest and those who do not ingest medicines, so storage practices alone cannot predict the likelihood of childhood poisoning.^{169,196}

One important caveat relates to the storage of nonpharmaceutical xenobiotics, particularly those in liquid form. These types of xenobiotics should never be transferred for storage to familiar household containers, such as food jars or wine or soda bottles; stored in areas low to the ground such as beneath sinks; or kept in cabinets that do not have child-resistant locks. Both children and adults have been unintentionally exposed to xenobiotics, such as sodium hydroxide, pesticides, hydrocarbons, and potassium cyanide, that was stored in bottles in the refrigerator.¹⁸¹ Many of the kerosene exposures reported from developing countries occur because the kerosene is stored in water bottles, jugs, or other containers in easily accessible locations. When the weather is hot, children may mistake the clear liquid kerosene for water.^{1,40,101}

HISTORY OF THE INGESTION

The appropriate management of any poisoned patient is influenced by the history of the exposure. Except in rare cases of child abuse-related poisoning, parents or guardians generally provide information to the fullest extent possible. As a rule, in the case of children, the xenobiotic and time of ingestion are known. However, the reported number of pills or volume of liquid ingested may not be as accurate. Clues to the amount ingested are the number of pills or volume of liquid in a bottle before and after an ingestion, the number of pills set out on the night table, or the area of a spot of liquid after a spill. When symptoms are suggestive of poisoning but the history is inadequate, information about possible exposure outside of the home, such as with a babysitter, grandparent, friend, or other relative, should be obtained because approximately 15% of childhood poisonings occur outside the home.^{81,132}

In contrast, adolescents may not be forthcoming when relating the history of an intentional ingestion, especially when they are depressed, suicidal, or concerned about the response of their guardian or parent. When caring for these patients, the clinician must use the history provided but should remain skeptical about the reported type and number of xenobiotics ingested, as well as the time of ingestion.

When a child may be the victim of abuse or intentionally poisoned by a parent or guardian, the health care provider must ensure that (1) the history of the poisoning remains consistent over time and among people providing the details of the event, (2) the child's clinical presentation is consistent with the history of the poisoning, and (3) the reported actions are consistent with the child's developmental level.

GASTROINTESTINAL DECONTAMINATION

Chapter 8 is devoted to a complete discussion of gastrointestinal (GI) decontamination. This section reiterates and emphasizes only a few important points.

As described earlier, children generally ingest small quantities of a single xenobiotic. For most of these ingestions, gastric emptying is unnecessary. Some examples of nontoxic ingestions are eating a crayon or the leaf of a jade plant, licking the cap of a household bleach container, or swallowing two adult-strength APAP tablets.

Orogastric lavage is the preferred method of gastric emptying when indicated for most serious ingestions. Small children can generally tolerate orogastric lavage with a large-bore 28- or 34-French tube; however, the smaller “large-bore” tubes may not be effective for removing large pills or fragments from the stomach of a small child. Placement of an orogastric tube is an unpleasant and frightening procedure for an infant or small child to undergo. Some local trauma may result from tube placement, and rarely, there may be more serious injury, such as esophageal perforation. Also, many children vomit during placement of an orogastric tube. Therefore, the use of orogastric lavage should be limited to cases in which the risk of significant morbidity or mortality is high, the likelihood of benefit is at least moderate, and the likely risk of injury to the child from the procedure is small. Orogastric lavage should never be used as a form of punishment. The patient should be intubated to protect the airway before orogastric lavage is used in a child with a diminished gag reflex or a depressed level of consciousness.

Previously, administration of syrup of ipecac to poisoned patients was considered a primary emergency intervention, and the availability of syrup of ipecac in the home was a primary tenet of pediatric anticipatory guidance. The AAPCC reports that the use of syrup of ipecac for case management declined from 13% in 1983 to 0.1% by 2005. This is not surprising because syrup of ipecac is contraindicated in cases associated with hemodynamic instability, seizures, or a depressed level of consciousness. Although syrup of ipecac is highly effective at making children vomit, the efficacy of preventing morbidity after an ingestion is questionable.

Even before the use of syrup of ipecac was abandoned, it had been used only infrequently in the ED management of poisonings, with lavage favored when evacuation of the stomach was considered important. However, it was only 10 years ago that it was still advocated for use at home at the direction of a poison center to avoid an unnecessary evaluation in an ED. However, in 2003, the American Academy of Pediatrics (AAP) recommended against the use of syrup of ipecac at home, and in 2004, the American Academy of Clinical Toxicology and the European Association of Poison Control Centres and Clinical Toxicologists recommended against the general use of syrup of ipecac for the management of poisoning.^{4,6} The reasons for the new recommendations include its unproven benefit, its adverse effects, its interference with and complication of subsequent ED evaluation, its abuse potential, and its administration in cases in which there is no indication or there is a contraindication because of lack of consultation with a poison center.

Activated charcoal (AC) is a current mainstay of poison treatment in EDs.^{3,35} Children generally will not drink AC willingly, although some children can be coaxed to do so if the AC is disguised in a baby bottle or soft drink container or sweetened with juice or sorbitol.¹⁹³ A nasogastric or orogastric tube may have to be inserted to administer AC. This can be a small-bore tube because it is not intended for lavage, although the smaller the bore, the more difficult it is to administer the thick slurry of AC. Placement of the tube, the presence of AC in the stomach, the effects of the xenobiotic, or the previous use of an emetic all may make the child vomit, making aspiration of AC or stomach contents a risk. For AC to be used safely in a patient who is comatose and who does not have a gag reflex, the patient should be intubated and the airway protected. Because of this risk, AC alone is unnecessary for a nontoxic or minimally toxic ingestion.

AC is available for home use.^{98,174} Administration of AC at home or by prehospital personnel allows for administration significantly earlier than can be achieved after arrival and evaluation in the ED.^{38,174} Although it would seem to have potential benefit as home therapy, AC is unpalatable, quite messy, and not always available; as a result, it has not achieved widespread use in the home.^{127,142} It is also unclear how well parents can administer AC at home.^{154,155,175} Whether the earlier administration of AC would affect outcome is unknown. If AC is to become a standard to replace syrup of ipecac for home therapy, it will require a substantial reeducation effort on the part of pediatricians, toxicologists, and pharmacists.

METHODS OF ENHANCED ELIMINATION

For consequential poisoning with xenobiotics such as methanol, ethylene glycol, salicylates, lithium, and theophylline, either hemodialysis or charcoal hemoperfusion is the optimal technique to enhance elimination, depending on the particular xenobiotic. These extracorporeal techniques can be performed on newborns or small infants in specially equipped centers with dedicated personnel. The primary limiting factor is the ability to obtain vascular access.^{18,48,50,182} However, even large centers that routinely do hemodialysis in children may not be able to manage very small infants. There has been a report of the use of peritoneal dialysis for the treatment of alcohol intoxication in a child,⁶⁹ but this technique is not generally recommended.

Exchange transfusion is occasionally used to enhance xenobiotic elimination. This technique might be useful when multiple-dose AC cannot be administered, the xenobiotic is poorly adsorbed to AC, or access to specialized hemodialysis

or hemoperfusion is not readily available. Exchange transfusion has been used successfully for poisoning by salicylates^{49,113} and theophylline.^{15,129,161} Another xenobiotic for which exchange transfusion may be a therapeutic alternative is chloral hydrate.⁹

XENOBIOTICS THAT MAY BE TOXIC OR FATAL IN SMALL QUANTITIES

When children ingest even small quantities of toxic xenobiotics, they are potentially ingesting large relative doses because of their small size. There are a number of xenobiotics that may cause significant toxicity or even death with as little as one pill or one teaspoonful.^{13,102} Table 32–4 lists these xenobiotics.

TABLE 32–4. Xenobiotics That May Cause Severe Toxicity to an Infant after a Small Adult Dose, a Single Pill, or a Small Volume

β-Adrenergic antagonists (sustained release)

Benzocaine

Bupropion

Calcium channel blockers (sustained release)

Camphor

Clonidine

Cyclic antidepressants

Diphenoxylate and atropine (Lomotil)

Methanol or ethylene glycol

Methylsalicylate

Opioids (buprenorphine, codeine, methadone, oxycodone)

Pesticides/Herbicides/Rodenticides

Phenothiazines

Quinine or chloroquine

Sulfonylureas

Theophylline

XENOBIOTICS THAT MAY CAUSE DELAYED TOXICITY IN CHILDREN

Several xenobiotics warrant particular concern because their effects may be significantly delayed. Classic examples are atropine–diphenoxylate (Lomotil)^{23,39,115} and sulfonylureas such as glipizide.^{67,134,178} Both of these xenobiotics may cause serious morbidity with initial symptoms or recurrence of symptoms delayed by as much as 24 hours after ingestion.

Children with real or possible ingestions of Lomotil or a sulfonylurea should be admitted for observation and monitoring even if they are asymptomatic because effects may not become apparent for 24 hours (Chaps. 38 and 53).

With the advent of new modified-release formulations of calcium channel blockers and β-adrenergic antagonists, concern for delayed toxicity and possibly death has become even greater.¹²³

XENOBIOTICS THAT CAUSE UNUSUAL OR IDIOSYNCRATIC REACTIONS IN CHILDREN

Benzyl Alcohol: Gaspings Syndrome

Benzyl alcohol is a preservative added to liquid pharmaceutical preparations; for small-volume medications administered to adults, the benzyl alcohol additive is quite safe (Chap. 55). However, at toxic doses, benzyl alcohol may cause respiratory failure, vasodilation, hypotension, convulsions, and paralysis. IV flush solutions containing benzyl alcohol were implicated as the cause of the “gasping syndrome” in sick newborns; the syndrome includes severe metabolic acidosis, encephalopathy, respiratory depression, and gasping.⁵ The association was made when infants with this syndrome were found to have elevated concentrations of benzoic acid and hippuric acid, metabolites of benzyl alcohol.^{27,63} Benzyl alcohol is metabolized by the conjugation of benzoic acid with glycine to form hippuric acid; this pathway may not be functional in premature infants. Benzyl alcohol administration has also been associated with kernicterus and intraventricular hemorrhage in premature infants.^{76,82} Although benzyl alcohol has been removed from many of the medications used for neonates, some preparations may still contain this agent.¹⁹¹

Imidazolines and Clonidine: Central Nervous System Effects

Imidazolines such as tetrahydrozoline, oxymetazoline, xylometazoline, and naphazoline are nonprescription sympathomimetics used as nasal decongestants and conjunctival vasoconstrictors (Chap. 49). Clonidine is an imidazoline derivative used as an antihypertensive (Chap. 63). In small children, these xenobiotics can cause central nervous system (CNS) depression, respiratory depression, bradycardia, miosis, and hypotension.^{12,112,194} The presumed mechanism of action is by stimulation of central α_2 -adrenergic and imidazole receptors. Although naloxone has been reported to reverse some of the CNS effects of clonidine, there are no reports of its successful use with the other imidazolines (Chap. 63).

Ethanol: Hypoglycemia

Ethanol is the primary component of alcoholic beverages, as well as a major constituent of many liquid preparations, such as mouthwash, vanilla flavoring, and perfume. Besides its well-known sedative–hypnotic effects, ethanol poisoning in children is associated with hypoglycemia because of reduced hepatic glycogen stores in children. Ethanol-induced hypoglycemia may cause seizures and may exacerbate the other CNS effects induced by ethanol poisoning. Hypoglycemia results from the inhibition of gluconeogenesis in the setting of alcohol poisoning. There does not seem to be a blood alcohol concentration threshold for the development of hypoglycemia, which has been reported with blood alcohol concentrations as low as 20 mg/dL⁴² (Chap. 80).

Chloramphenicol: Gray Baby Syndrome

Chloramphenicol is a broad-spectrum antibiotic that has been used in children because of its activity against *Haemophilus influenzae*. It has largely been replaced by other antibiotics in the United States because of its association with aplastic anemia. When administered at high doses, chloramphenicol can produce the “gray baby syndrome,” which includes abdominal distension, vomiting, metabolic acidosis, progressive pallid cyanosis, irregular respirations, hypothermia, hypotension, and vasomotor collapse. Although these effects occur primarily in premature newborn infants, they may also occur in older children and adults (Chap. 57).

Gray baby syndrome is associated with serum concentrations greater than 100 mg/L. Increased chloramphenicol concentrations may result from (1) inadequate conjugation of chloramphenicol with glucuronic acid because of inadequate activity of glucuronyl transferase in the newborn liver and (2) decreased renal elimination of unconjugated chloramphenicol. The exact mechanism of toxicity is unknown; there is speculation that free radicals produced during the metabolism of chloramphenicol may interfere with mitochondrial function.⁷⁸

MEDICATION ERRORS

Ever since the publication of the Institute of Medicine’s report titled *To Err is Human* in 1999, increasing attention has been paid to the issue of medical errors in medicine.⁹⁰ Although most of the research regarding medication errors has focused on adults (Chap. 140), this problem also affects children. Remarks in this section are generally limited to the pediatric literature.

Approximately 125,000 exposures each year are classified by the AAPCC as therapeutic errors, accounting for approximately 6% of exposures in children younger than 6 years of age, 24% in children 6 to 12 years of age, and 11% in adolescents. For 2007 to 2011, there were a total of 26 deaths attributed to therapeutic errors, representing 3% of all reported deaths in children and adolescents. Eight percent of the AAPCC-reported fatalities in young children were related to therapeutic errors, but only 1% of the adolescent fatalities were related to therapeutic errors. Of children younger than the age of 6 years, approximately 40% of the errors resulting in severe injury or death occur in children younger than the age of 1 year.¹⁸⁴

Medication errors may occur at any phase of a process that includes ordering, order transcription, pharmacy dispensing, preparation and administration of the medication, and monitoring of medication effects. In fact, the same types of errors can

occur at different points in the process. [Table 32–5](#) lists the types of errors that can occur, and [Table 32–6](#) provides some examples of errors.

TABLE 32–5. Medication Errors

1. Wrong patient—someone else’s drug
2. Wrong drug
 - a. Wrong individual drug
 - b. Wrong formulation
 - c. Known allergy
 - d. Known drug–drug interactions
 - e. Wrong indication
 - f. Contraindication
 - g. Expired
 - h. Deteriorated
3. Wrong dose
 - a. Miscalculation
 - i. Decimal point error
 - ii. Wrong formula
 - iii. Right formula using wrong dose, frequency, units, weight
 - iv. Pound–kilogram confusion
 - v. Mg–g units confusion
 - vi. Dilution error
 - b. Appropriate individual dose divided into multiple doses
 - c. Total daily dose for an individual dose
 - d. Wrong intravenous infusion rate
 - e. Measuring error
4. Wrong route
5. Wrong frequency
 - a. Increased or decreased dosing interval
 - b. Omitted, delayed, or added dose
 - c. Delay or failure to supply
6. Transcription errors
7. Documentation (order, prescription, transcription, logs)
 - a. Illegible
 - b. Incomplete or missing information (weight, signature, maximum daily dose, stop date)
8. Monitoring
9. Miscellaneous
 - a. Wrong label
 - b. Wrong information or advice
 - c. Failure to detect error
 - d. Breast milk exposure

Data based on Kaushal R, Bates DW, Landrigan C, et al: Medication errors and adverse drug events in pediatric inpatients. *JAMA*. 2001;285:2114–2120; Lesar TS: Errors in the use of medication dosage equations. *Arch Pediatr Adolesc Med*. 1998;152:340–344; and Wilson DG, McArtney RG, Newcombe RG, et al: Medication errors in paediatric practice: insights from a continuous quality improvement approach. *Eur J Pediatr*. 1998;157:769–774.

TABLE 32–6. Examples of Medication Errors

1. **Wrong drug.** In one nursery, an epidemic mimicking neonatal sepsis was caused when racemic epinephrine was inadvertently administered instead of vitamin E because both drugs were manufactured by the same company, distributed in nearly identical bottles, and stored near each other inside the nursery refrigerator.¹⁷³
2. **Wrong drug formulation.** APAP suppositories (120 mg) were ordered for a toddler, but adult-strength suppositories (650 mg) were distributed and administered every 4 hours. The child developed hepatotoxicity requiring hospitalization and therapy (Chap. 35).
3. **Wrong dose.** A 1 kg premature infant required sedation for a diagnostic study. A high dose of chloral hydrate, 100 mg/kg, was miscalculated to be 1 g (1000 mg) instead of 100 mg. The child had a cardiopulmonary arrest and died. When drugs require milligram per kilogram dosing, it is easy to make decimal mistakes in the calculation or in the transcription.
4. **Wrong route.** A 17 month-old girl with a central venous line (CVL) and a gastrostomy tube required an upper gastrointestinal series. Barium sulfate was inadvertently injected into the CVL instead of the gastrostomy tube. The patient had several episodes of vomiting and developed fever and rigors but ultimately recovered.¹⁷²
5. **Wrong dose.** A patient had the dose of cyclosporine changed from 10 mg to 7 mg twice daily. The child received 70 mg (0.7 mL of solution) instead of 7 mg (0.07 mL). When the prescription was refilled, the parents received a 5 mL syringe to use instead of a 1 mL syringe they had used previously.⁴⁴

Most of the analyses of medication errors have occurred in inpatient settings. The reported frequencies of medication errors vary widely—from 0.47% to 5.7% of written orders and from 0.51 to 157 per 1000 patient-days.^{55,62,77,84,87,151} The variance largely depends on whether the definition of “error” does or does not include prescribing errors, regardless of whether or not they are corrected, and whether potential, or only actual, adverse drug events are included. The reported frequencies also vary depending on whether there is active case finding or whether there is only voluntary reporting.

In a 2001 study of pediatric inpatients in which orders were actively monitored for a 6-week period, 5.7% of 10,778 prescriptions had errors in the order for the medication, transcription of the order, dispensing or administration of the medication, or monitoring of medication effects (56 per 100 admissions, 157 per 1000 patient-days);⁸⁷ 1.1% could have potentially caused an adverse effect (10 per 100 admissions, 29 per 1000 patient-days). Eighty-four percent of the errors occurred during the ordering or transcription phase, so most of the errors were intercepted and corrected before drug administration. There were 26 true adverse drug events, but only five were considered preventable errors (0.05%, 0.52 per 100 admissions, 1.8 per 1000 patient-days). Although the overall error rate was similar to that reported by the same group in a study of adults, the rate of errors that could potentially have caused harm was three times greater; 41% of the potentially harmful errors were not intercepted. However, one review suggests that the prescription error rate is higher in adults than in children.¹⁰¹

Generally, error rates are higher in intensive care units, where the sickest patients are cared for; such patients often receive multiple medications with complex administration regimens.^{55,77,87,135,151,186,195} Results similar to those from inpatient settings have been reported in pediatric EDs.^{62,95,153,159,164}

The studies cited suggest that the frequency of significant errors leading to significant adverse drug events is low; however, even a low frequency applied to a large population of patients could result in a large number of patients being harmed. The most important outcome of the analysis would be to try to reduce the overall number of errors to reduce the number of potential and actual adverse drug events.

The causes of medication errors are numerous, varied, and complex; they are organizational, environmental, and personal, which includes factors such as the level of training, knowledge and competence, the time of day, workload, staff interactions, communications, number of distractions or interruptions, ambient noise, and drug formulation and drug packaging.^{41,57,65,90,189} (Chap. 140).

Children may be placed at increased risk of a medication error for several reasons: (1) someone other than the child administers the medication, so there is little opportunity to prevent or limit drug administration; (2) a young child cannot warn practitioners about possible problems such as allergies; (3) a young child cannot inform practitioners when he or she is experiencing an adverse event; (4) medication ordering and administration in children frequently requires dose calculations; (5) inexperienced practitioners may be uncomfortable with pediatric dosing or related calculations; and (6) incorrect measurement or dilution of concentrated stock solutions may yield a small volume, which is not perceived as containing a relatively large dose of medication.^{32,44,65}

One of the most common errors is prescription, preparation, or administration of an incorrect dose, particularly in children, for whom almost every prescription requires knowledge of the patient’s weight and a calculation of a weight-based dose.^{87,96,100} In addition, even the milligram per kilogram dose may vary depending on the age of the patient or the diagnosis. Although pediatric doses are generally determined on a milligram per kilogram basis, if the weight is recorded in pounds and this weight is used in the calculation, there will be a built-in twofold error. Calculation errors also occur when drug preparation requires dilution of a concentrated stock solution or special compounding.¹⁸⁴ Further confusion can

arise when mg is written as or misinterpreted as mL or μg in a calculation or vice versa.⁴⁰

When an extra zero is added or a required zero is omitted from calculations, written or verbal prescriptions, or in dispensed and administered medications, a 10-fold error occurs. These large errors are common and result in significant under- or overdosing; 10-fold errors have been reported in testing scenarios, case series, and case reports.^{47,92,93,96,139,147,151,184} These errors are of particular concern because the risk of toxicity generally increases with significant overdose.

Because the causes of medication error are numerous and complex, the solutions must be multifaceted and interdisciplinary. The approach to the problem is contained within the field of human factors research and potentially requires changes in individual factors such as knowledge; environmental factors such as interruptions; and system problems such as how medications are ordered, stocked, and dispensed^{90,177,189} (Chap. 140).

The most commonly recommended solutions to reduce the frequency of medication errors are computerized physician order entry (CPOE) with clinical decision support systems^{85,185}; ward-based clinical pharmacists; and improved communication among and between all levels of medical, nursing, and pharmacy staff.^{86,99,141,177} In one of the studies cited earlier, it was estimated that these three solutions together could have prevented more than 90% of the potential errors,⁵⁶ although the effect of interventions other than CPOE has generally not been studied.

In its simplest form, CPOE eliminates errors related to legibility. Decision support adds the ability to check a prescription against age, weight, dose, allergies, and drug–drug interactions, but it may not prevent ordering the wrong drug or dose, so there is still a need for education and human oversight in addition to other safeguards. The implementation of CPOE is generally associated with at least some reduction in errors related to medication ordering, although an effect on morbidity or mortality has not yet been demonstrated.^{1,185} Sometimes there are unanticipated consequences associated with computerized systems.^{91,116,188}

In the future, all inpatient medication orders and outpatient prescriptions may be transmitted electronically, but until that time, it will be necessary to ensure that prescriptions are written legibly and correctly. The Joint Commission and many other groups have issued recommendations to reduce errors in medication ordering (Chap. 140).

Standardized tests of the math skills necessary to calculate doses and administer medications have demonstrated deficiencies in both nursing and physician groups.^{17,21,126,130,133,146,152} Tests of this nature may be a means of identifying practitioners at risk for making calculation errors, highlighting areas in need of remediation, and serving as ongoing educational tools.

As described earlier, there may be an increased risk of medication errors in critical care areas because of severity of illness and intensity of medication therapy. In many cases, such as during resuscitations, critically ill patients require immediate therapy, verbal orders are common, and there is often insufficient time to carefully review all of the particulars related to medication ordering and administration.^{45,62,96,108,131}

Critical care areas, including the ED, benefit from having precalculated dosing charts available for resuscitation medications and for other commonly prescribed medications; this is a recommendation of the American Heart Association.⁷ Many clinical units have developed their own dosing schemes. Commercial products, such as the Broselow-Luten system, are also available and have been shown to reduce the number of medication errors in simulated^{2,107,109,160} and actual resuscitations.¹⁵⁰ There has been some controversy related to the ability of these length-based commercial products to accurately predict the weights of children from diverse domestic and international populations for the purpose of medication dose calculation.^{110,122}

The previous discussion has been almost exclusively related to hospital-based medication use, but significant errors also may occur in outpatient settings. Antipyretics are among the most frequently recommended medications for children. Although significant toxicity after unintentional ingestions in toddlers is now rare, administration of multiple supratherapeutic doses of APAP is common and can cause significant hepatotoxicity.⁹⁴

In fact, many parents have difficulty calculating the appropriate dose of APAP and measuring out the appropriate amount after it is calculated despite having received instructions and graduated cups or oral-dosing syringes.^{68,111,119,167,171} Relevant factors related to these errors include the characteristics of the instructions regarding medication measurement and administration, the health literacy of caregivers, and the accuracy of different measuring devices.

Two of the most commonly used measuring devices are also the most inaccurate—the teaspoon and the graduated cup.^{153,199} The household teaspoon is not standardized for volume and can easily be confused with a household tablespoon.¹¹¹ APAP and ibuprofen elixirs are typically packaged with a graduated cup for administration even though graduated syringes are considered the most accurate of the measuring instruments available and are recommended by the AAP for young children. In addition, the instructions and measuring devices distributed with these products, as well as other nonprescription medications, are highly variable and inconsistent.²⁰⁰

Health literacy and health numeracy are becoming increasingly understood factors with regard to the safe and effective delivery of health care in general and the reduction of the rate of medical errors in particular. Health literacy plays a key

role in a caregiver's ability to read and understand instructions about and labels on prescriptions and nonprescription medications.¹⁶⁴ The labels on medication containers are not standardized with respect to the layout and placement of information or the use of abbreviations or units of measure, may be printed in small fonts that are physically difficult to read, and may be difficult to understand by people with lower health literacy or limited English proficiency.^{106,200,202} Instructions for medication administration have the same problems. Visual cues using pictograms in the instructions or color-coded or premarked syringes are practical ways to improve the accuracy of parental medication dosing.^{58,198,201}

INTENTIONAL POISONING AND CHILD ABUSE

Intentional poisoning of children is an unusual, but significant, form of child abuse. Most cases are related to pathologic characteristics of the parent or guardian and have been categorized as (1) undifferentiated child abuse, neglect, or impulsive acts under stress; (2) factitious illness (Munchausen syndrome by proxy {MSBP}); (3) overt parental psychosis; and (4) the Medea complex, or the vengeful killing of a child out of spite for one's spouse.^{74,149,179} Rare cases of intentional poisoning may be related to bizarre childrearing practices.

Intentional poisoning is rarely suspected unless the patient dies and an autopsy is performed, a wide-ranging drug screen is ordered, or the history is bizarre enough to raise suspicions. In many cases in which children are later found to be poisoned, the initial diagnoses were sepsis, meningitis, seizures, intracranial hemorrhage, gastroenteritis, apnea, apparent life-threatening events, or metabolic derangements.⁷⁴ In addition to many pharmaceuticals, salt, pepper, water, caffeine, ethylene glycol, herbs, plants, and traditional remedies have been used to poison children.^{46,74} Although the death rate from unintentional poisoning in children is much less than 1%, the death rate from "malicious" intentional poisoning may be as high as 20% to 30%.^{46,74,179}

Intentional poisoning may be associated with other forms of abuse; approximately 20% of poisoned children may have evidence of physical abuse.^{46,74} Of children presenting to EDs after presumed unintentional poisoning, 36% had previous ED visits for trauma, 7% for poisoning, 6% for both trauma and poisoning, and 1.4% for failure to thrive. At the time of the visit, only 7% were evaluated for possible abuse, and 2.7% were considered neglected.⁷⁴ These data do not prove an association between poisoning and physical trauma; however, in some children, repeat episodes of trauma or poisoning may be a manifestation of significant intrafamilial stress. Health care providers must remain vigilant to the possibility that a presumed unintentional poisoning may have been "malicious" intentional, especially in the setting of a repeat ingestion or when there have been previous evaluations for trauma.

Substance abuse by a parent or guardian may play a role in unintentional or intentional poisoning of children. Children have been poisoned with cocaine or phencyclidine by passive inhalation of side smoke,^{16,73,124,157,192} unintentional ingestion,^{88,140} and rectal administration,¹³⁶ as well as through breast milk.³³ Children have been given doses of alcohol, methadone, and other xenobiotics to quiet them or to prevent withdrawal.^{42,75,138} There are reports of babysitters blowing marijuana smoke into babies' faces to "get them high" or to quiet them.¹⁵⁸

In 1977, the term Munchausen syndrome by proxy was first used to describe a condition in which a parent or guardian, typically the mother, fabricates a history of nonexistent disease(s) in a child or creates the signs and symptoms of disease in a child (factitious illness).^{120,121,149} This is usually a manifestation of the parent's complex psychiatric illness, which may include Munchausen syndrome itself.^{24,66,156} There may be only a fine line separating MSBP from an intentional poisoning with intent to harm or kill a child. However, regardless of the specific intent, this condition is considered a form of child abuse.

Over the years, child protection experts have tried to develop more specific terminology than MSBP. In light of the fact that this entity involves two individuals—the child victim and the adult perpetrator—the American Professional Society on the Abuse of Children recommends that the child victim be diagnosed with "pediatric condition falsification" and that the psychiatric diagnosis of "factitious disorder by proxy" be applied to the adult perpetrator. The diagnosis of MSBP requires that both criteria be met.^{10,156}

A child's fabricated illness may lead to multiple medical evaluations by several different physicians, frequent hospitalizations, unnecessary surgeries and diagnostic testing, unneeded prescribing and administration of medication, and at times even the death of the child. Administration of medications to the child by the adult perpetrator is frequently how a particular set of signs and symptoms is created. Xenobiotics used to create factitious illness have included analgesics, antidepressants, insulin, syrup of ipecac, Lomotil, phenothiazines, sedative-hypnotics, warfarin, phenolphthalein, and hydrocarbons.¹⁴⁸ Several warning signals may suggest a diagnosis of MSBP (Table 32–7).

TABLE 32–7. Factitious Illness (Munchausen Syndrome by Proxy): Suggestive Characteristics in Clinical Situations

1. The child has a persistent or recurrent illness that cannot be explained.
2. The history of disease or results of diagnostic tests are inconsistent with the general health and appearance of the child.

3. The signs and symptoms cause the clinician to remark, “I’ve never seen anything like this before!”
4. The signs and symptoms do not occur when the child is separated from the parent.
5. The parent is particularly attentive and refuses to leave the child’s bedside even for a few minutes.
6. The parent develops particularly close relations with hospital staff.
7. The parent seems less worried than the physician about the child’s condition.
8. Treatments are not tolerated (eg, intravenous lines fall out frequently, prescribed medications lead to vomiting).
9. The proposed diagnosis is a rare disease.
10. “Seizures” are unwitnessed by medical staff and reportedly do not respond to any treatment.
11. The parent has a complicated medical or psychiatric history.
12. The parent is or was associated with the health care field.

Data from Meadow R: Munchausen syndrome by proxy. *Arch Dis Child*. 1982;57:92–98.

In one illustrative case of MSBP, a 29 month-old boy who had undergone a previous appendectomy was hospitalized multiple times for vomiting, diarrhea, and dehydration.⁶⁴ Evaluation included multiple blood and stool analyses, a gastric pH probe, endoscopy, upper GI series, computed tomography, and magnetic resonance imaging. On the fourth admission, a small bowel obstruction was identified, and the child had lysis of adhesions. Nonetheless, symptoms recurred every 2 to 4 months, necessitating hospitalization. The child failed to thrive and required a nasoduodenal tube for feeding, which frequently became dislodged. The child went on to have a jejunostomy tube and a permanent central venous catheter placed. Eighteen months after his initial presentation, the child presented in congestive heart failure with evidence of cardiomyopathy. A urine screen identified emetine and cephaline, components of syrup of ipecac. The child was removed from his home to protective custody after which he recovered and remained asymptomatic on a regular diet.

Siblings of children evaluated and treated for poisoning may also have suffered from factitious illness. In addition, significant psychiatric problems may be manifested by the victim, parents, and siblings.^{25,118,156,162}

Child abuse or neglect must be part of the differential diagnosis of any case of childhood poisoning. Intentional poisoning should be considered for,^{74,75}

- An “ingestion” in a child younger than one year of age
- A case with a confusing history or presentation
- A child with a previous poisoning or a child whose siblings have previously been evaluated for poisoning
- A child with a previous presentation for a rare or unexplained medical condition
- A child with apnea, unexplained seizures, or an apparent life-threatening event
- A massive ingestion by a small child
- An ingestion of multiple xenobiotics by a small child
- An exposure to substances of abuse
- An intoxication with a xenobiotic to which a child could or would not typically have access
- “Accidental ingestions” in a school-age child
- A history of previous trauma, child abuse, or neglect
- Sudden infant death syndrome or an unexplained death

These considerations of child abuse notwithstanding, rare diseases do occur. One child’s rare, inherited metabolic disorder, methyl malonic acidemia, was misdiagnosed as ethylene glycol poisoning because of the chromatographic appearance of the metabolite propionic acid, which was similar to that of ethylene glycol.¹⁶³

SUMMARY

- Children are frequently exposed to potentially toxic xenobiotics; fortunately, most childhood exposures are ingestions of nonpoisonous xenobiotics or small nontoxic quantities of potentially toxic xenobiotics.
- When a child sustains a significant toxic exposure, management follows general toxicologic principles.
- Although most childhood exposures are unintentional, the clinician should be alert to the possibility of intentional poisoning of a child with pharmaceutical or household products.
- The normal development of children places them at risk for unintentional ingestions. A chaotic home environment or a disorganized social structure may compound these risks.
- Small size puts children at increased risks for medication dosing and dispensing errors, and their immature metabolic processes may lead to unexpected toxicity from pharmaceuticals.
- Toxicologists should encourage parents to provide as safe a home environment as possible to prevent unintentional ingestions and must encourage practitioners to exercise special vigilance when administering medications to children.

33 GERIATRIC PRINCIPLES

Judith C. Ahronheim and Mary Ann Howland

PREVALENCE, LETHALITY, AND UNDERRECOGNITION OF TOXIC EXPOSURE

The population is aging steadily across the world. In the United States, people older than 65 years of age comprise not only an increasing proportion of the population at large (13%) but also an increasing proportion of patients seen in medical practices. Compared with all other age groups, patients older than 65 years of age account for one-fourth of emergency department (ED) ambulance arrivals with the highest proportion of patients in EDs triaged as emergent¹⁰² and the highest number of hospital and intensive care unit admissions.¹¹⁷

Although the elderly account for only a small minority of toxicologic exposures, when exposed, they have a high mortality rate. Among exposures reported to the American Association of Poison Control Centers (AAPCC), the fatality ratio for adults (ie, number of cases divided by number of deaths) exhibits a bimodal pattern, declining after age 30 until age 60, when it again rises (Chap. 136). The factors associated with the increased fatality ratio after age 60 are complex but are likely due in part to physiologic vulnerability.

In a separate study, seven specific pharmaceuticals were selected from the AAPCC database for analysis based on their prevalent use and potential toxicity from 1995 through 2002. These pharmaceuticals were theophylline, digoxin, benzodiazepines, tricyclic antidepressants (TCAs), calcium channel blockers, acetaminophen (APAP), and salicylates.¹¹⁴ The death rate from intentional or unintentional exposure to these pharmaceuticals was found to increase by 35% for each decade of life after age 19 years.¹¹⁴ Although prescribing for some of these drugs has dramatically decreased over time, specific categories continue to pose problems for patients in the latest decades of life.^{14,62}

Exposures reported to the AAPCC may underestimate the serious consequences for elderly people exposed to xenobiotics that are toxic or potentially toxic. Data from the National Electronic Injury Surveillance System–Cooperative Adverse Drug Event Surveillance Project (NEISS-CADES) indicate that patients aged 65 years and older accounted for 25% of estimated visits related to adverse drug events (ADEs) and almost 50% of such visits requiring hospitalization or prolonged monitoring in the ED during 2004–2005.¹⁵ Furthermore, the incidence of ADEs increases steeply from age 65 years through the tenth decade of life.¹⁵ More recent NEISS-CADES data indicate that almost 50% of elders who required emergency hospitalization as a result of ADEs are people 80 years of age or older.¹⁴ The problem may be even greater than the NEISS-CADES study suggests, because their data did not capture ADEs in patients treated or dying outside of EDs, ADEs that could only have been recognized after admission, or ADEs that might be erroneously diagnosed as non-drug-related problems.

Toxic exposures in the elderly may be underrecognized for several reasons. First, because of pharmacokinetic and pharmacodynamic changes that occur with aging,³³ which a “standard” therapeutic dose may produce as an unexpected serious effect. Second, the presentation of disease, including drug toxicity, is often atypical in the elderly.⁷¹ For example, falls may be a presenting sign of toxicity in the elderly, with prescribed sedative–hypnotics, opioids, antipsychotics, antidepressants, and certain cardiovascular xenobiotics among the most often associated with an increased risk of falling.^{46,107,115,133}

If the patient is cognitively impaired and the fall is unwitnessed, the immediate consequences of the fall may be adequately addressed, but the xenobiotic and primary etiology causing it may not.⁸⁰ Another important syndrome in older patients is delirium, which may be caused by many factors but is a common presentation of xenobiotic toxicity.⁵⁹ A large variety of xenobiotics may cause mental status changes, which may mistakenly be attributed to non-xenobiotic-related causes in the elderly.¹²⁸ Conversely, altered mental status may be unrecognized^{67,89} or misdiagnosed—for example, as Alzheimer’s disease or psychiatric illness.¹¹¹ A striking case of drug-induced mental status changes is represented by a previously normal 66 year-old man who developed psychosis and attempted suicide after taking increasing doses of dextromethorphan-containing cough syrup for a respiratory infection. The patient was treated with psychiatric medications, and several months elapsed before providers realized that his behavior was xenobiotic-induced rather than due to a primary psychiatric condition.⁹³

Finally, the presentation of drug toxicity may be delayed in elderly individuals. Drugs with long half-lives may not reach a steady state and hence not achieve peak effects until days after the drug therapy is initiated. In some older patients, the active metabolite of flurazepam, desalkylflurazepam, has a half-life of up to 100 hours or longer, which requires days to achieve a steady state.⁵³ When peak effects are delayed in this way, drug toxicities may easily be mistaken for non-xenobiotic-related illnesses.

Table 33–1 lists xenobiotics commonly responsible for toxicity in the elderly.

TABLE 33–1. Xenobiotics That Pose an Increased Risk of Toxicity in the Elderly^a

Anticholinergics
Anticoagulants
Antidepressants
Antipsychotics
Cardiovascular medications
β-Adrenergic antagonists
Calcium channel blockers
Digoxin
Ethanol
Insulin secretagogues
Magnesium and phosphate containing laxatives
Nonsteroidal antiinflammatory drugs
Opioids
Salicylates
Sedative–hypnotics

^aIn addition, polypharmacy may lead to toxicity as a result of diverse drug–drug interactions.

SUICIDE AND INTENTIONAL POISONINGS

The risk of suicide in men increases with age in a bimodal distribution, rising steadily after age 70. Although data for individual ethnic groups are limited, white men have a substantially higher risk of suicide than age-matched cohorts among the African American population.²⁵ Another high-risk group appears to be Native American and Alaskan Native men, although the number of deaths from all causes in elderly men and certain other groups is too low to make meaningful comparisons.²⁵ Among people 65 years of age and older in the United States, white men have the highest rate of suicide of all groups, with almost 32 suicides per 100,000. The rate in the next highest risk group, Asian/Pacific Islander men, is almost 15 suicides per 100,000.²⁵ In women, the suicide rate peaks in midlife and then declines. However, for all age groups, women have a much lower rate of suicide than men; in 2010, for all races combined, the rate for men was 29 suicides per 100,000 and for women was 4.2 suicides per 100,000.²⁵

In the United States, firearms account for far more suicide-related deaths than do poisonings or other methods, particularly in men. The proportion of deaths due to firearm increases steadily after age 50, among men; by age 70 more than 75% of male suicides are by firearms, when all races are combined.²⁵ Suicides by poisoning are much less common in men than women at all ages. In women, poisonings account for similar or greater proportions of suicide than firearms.

Xenobiotic overdose is an important factor in suicide attempts by the elderly of both sexes.⁴⁷ Although less likely than men to complete suicide, women are more likely to attempt it.²⁶ The male-to-female ratio of suicide attempts narrows with increasing age, and in the oldest age groups, men attempt suicide slightly more often than women, when all methods of

attempted suicide are considered (Chap. 27).^{26,124}

Geographic and cultural factors also determine the method of suicide. In countries other than the United States, firearms are much less frequently used to commit suicide at any age, with suicide by oral overdose, toxic inhalation, or hanging comprising a much greater proportion.^{2,130} Among the elderly, the pattern of xenobiotics responsible for suicidal deaths may be changing because selective serotonin reuptake inhibitors are increasingly prescribed for depression instead of TCAs.²⁰ In the United States, higher suicide rates are associated with greater use of TCAs than non-TCA antidepressants,⁵¹ which could be related to greater lethality of TCAs in overdose or poorer tolerability of TCAs leading to nonadherence and enhanced suicide risk. In a Swedish study examining autopsy-confirmed suicides that included analysis of legal xenobiotics, the incidence of suicidal fatalities attributed to benzodiazepines was reported to be increasing despite a marked decrease in benzodiazepine prescriptions.²⁰ Overdose of benzodiazepines is rarely fatal unless it is accompanied by alcohol or another toxin or occurs in the presence of serious medical conditions.⁴⁰ However, the likelihood of fatality from an overdose of benzodiazepine taken alone increases markedly with each decade of life,¹¹⁴ perhaps because benzodiazepines in frail elderly people commonly lead to secondary morbidity and mortality from aspiration pneumonia, falls including hip fracture, and other medical complications that may be the proximate cause of death in the case of overdose.

Notably, flunitrazepam and nitrazepam, the two most frequently implicated in single benzodiazepine suicides in Sweden,²¹ are not available in the United States. However, single-drug suicides have been reported with other benzodiazepines that are available, such as flurazepam, triazolam, diazepam, and oxazepam.^{21,92,94}

SUBSTANCE ABUSE IN THE ELDERLY

Substance abuse declines with age⁴² but is important to consider in older adults under relevant clinical circumstances. Alcohol is the most common substance of abuse in people older than age 65 years. However, in recent years, an increase in the use of illicit xenobiotics and prescription drug misuse has been documented among older adults.¹⁴⁷

Currently, this change is largely noted in adults 50 to 64 years of age, as opposed to those 65 and older;¹²⁷ however, with increasing numbers of people entering the seventh decade of life (including those with past history of abuse disorders), illicit and nonmedical use is expected to increase substantially in older age groups. Unfortunately, a strong case can be made that middle-aged substance abusers have an “accelerated rate of biologic aging” than their nonabusing peers⁷³ and may be less likely to survive into the seventh decade, or, if they do, may be frailer than their same-age peers. However, approximately 22% of people 65 years of age and older use one or more prescription medications with abuse potential, including opioids and other central nervous system depressants.¹²¹

Analgesics are among the most commonly prescribed group of drugs among elderly people, second only to cardiovascular drugs. In one survey of community residing elderly, 23%, 21%, and 52% of those aged 65 to 74, 75 to 84, and 85 and older, respectively, had some exposure to opioids.⁹⁹ Although only a small proportion of people who take opioids are likely to abuse them, concern exists that long-term use could ensue once a prescription is written. In a recent study of elderly opioid-naïve patients undergoing low-risk surgery, those who received a prescription within a week of surgery were 44% more likely to become long-term users within the first year than those who were not given an opioid.³ Although the surgeries themselves were largely for conditions not associated with chronic pain, one cannot conclude that opioid use constituted “misuse,” because the study did not report specific reasons for the ongoing analgesic use. Notably, new users of nonsteroidal antiinflammatory drugs (NSAIDs) were far more likely than opioid users to continue analgesic use in this elderly group of patients,³ who would have been likely to experience chronic pain from a variety of causes.²⁸

Abuse of alcohol or other xenobiotics may be a continuation of long-term habits, but some individuals may first begin later in life.⁷⁵ Substance abuse in late life is probably underrecognized and underreported.¹¹² In one Illinois study of patients presenting to a trauma facility, only 5% of those aged 65 years and older were tested for alcohol or other substances, but among those younger than age 65, 22% were tested for alcohol and 29% for other xenobiotics.¹⁴⁹ Among elderly patients presenting to trauma facilities a large majority have a blood alcohol concentration (BAC) of 80 mg/dL or above.^{118,149} Such results, while similarly found in nonelderly trauma patients,¹⁴⁹ have different implications in the older adult, reflecting a smaller amount of alcohol ingested,^{134,138} owing to changes in body composition, and a greater impact on cognitive and motor function, owing to a diminished tolerance for alcohol (Table 33–2).

TABLE 33–2. Pharmacokinetic Considerations in the Elderly

	Young	Elderly	Effect on Kinetics
Fat (% of body weight)	15	↑30	↑Vd for xenobiotics distributing to fat (amitriptyline, diazepam)
Intracellular water (% of body weight)	42	↓30	↓Vd for water soluble xenobiotics
Muscle (% of body weight)	17	↓12	↓Vd for xenobiotics distributing into lean tissue (APAP, caffeine, digoxin, ethanol)
Albumin (g/dL)	4	↓With acute or chronic illness	↑Free concentrations of xenobiotics if > 90% bound to albumin, especially in overdose; interpretation of serum concentration altered
Liver	Normal	↓Size ↓Hepatic blood flow	Liver enzymes not predictive of compromise; concentrations of xenobiotics with high extraction (propranolol, triazolam) may increase; ↓hepatic oxidation (diazepam, chlordiazepoxide)
Kidney	Normal	↓Renal blood flow ↓GFR ↓Tubular secretion	↑Accumulation (lithium, aminoglycosides, N-acetyl procainamide, ACE inhibitors, cimetidine, digoxin, opioid metabolites)

ACE = angiotensin converting enzyme; APAP = acetaminophen; GFR = glomerular filtration rate; Vd = volume of distribution.

Elderly patients who are tested for BAC may also have positive urine toxicology screening results, although this occurs less often than in younger adults.¹⁴⁹ In one study, the most common xenobiotics detected in the elderly were benzodiazepines, opioids, and barbiturates,¹⁴⁹ which, like alcohol, are more likely to impair older than younger adults. The failure to consider use of these xenobiotics, whether illicit, nonprescription, or prescription, may have serious consequences. When admitted to hospitals, if a careful history is not elicited, withdrawal from these xenobiotics may be missed or misdiagnosed and be inappropriately managed as a result. Given the ongoing “graying” of the “baby boom” generation, greater vigilance will be needed and screening used appropriately.

Some caveats are in order when it comes to the older alcoholic at risk for withdrawal. Studies suggesting a longer duration or greater severity of the syndrome in the elderly have been criticized for their small size, retrospective nature, and absence of middle-aged comparison groups.⁷⁹ However, vigilance is called for because delayed assessment could lead to greater morbidity.⁴⁵ “Hypoactive” delirium, as opposed to typical delirium tremens, may occur, but this could be related to benzodiazepine use, because age-related enhanced sensitivity to these xenobiotics could lead to greater sedation and delirium in elderly who are being treated for withdrawal. Some clinicians may recommend shorter acting benzodiazepines, such as lorazepam rather than chlordiazepoxide,¹¹³ because the latter and its metabolites may be particularly long acting in the elderly and may cause progressive and excessive sedation as the drug and metabolites accumulate. Long-acting benzodiazepines, moreover, are more often associated with injury, including fractures, than short-acting benzodiazepines.¹³¹ Regardless of which benzodiazepine is used for alcohol withdrawal, careful monitoring with symptom-triggered dosing is generally preferable to a fixed-dose schedule in elderly patients, as in all other patients being treated for alcohol withdrawal.

PHARMACOKINETICS

Age-related pharmacokinetic changes have important clinical implications for elderly patients. The most consistent pharmacokinetic change that occurs with aging is a decrease in kidney function. Glomerular filtration rate (GFR) declines, on the average, by 50% between the ages of 30 and 80 years^{37,116} and cannot be accurately predicted by serum creatinine, which does not increase significantly with age,¹¹⁶ because muscle mass, the source of serum creatinine, declines with age.^{81,103}

Because it is impractical and often difficult to measure 24-hour creatinine clearance before instituting therapy with a renally excreted xenobiotic, clinicians commonly estimate creatinine clearance using age-adjusted formulas or nomograms. Frequently applied formulas are fairly predictive of GFR when kidney function is stable.¹⁰¹ However, age-related declines in GFR are not universal, and limited data from longitudinal studies suggest that as many as 33% of elderly individuals do not experience this age-related decline.⁹¹ Conversely, predictive formulas could significantly overestimate actual creatinine clearance in chronically ill, debilitated elderly people, especially those with chronic kidney disease (CKD).⁸⁴ Modifications to the Cockcroft-Gault equation to correct for body surface area^{69,119} and obesity¹⁴⁴ are proposed to better reflect kidney function (Table 28–7). However, anthropomorphic measurements are unreliable in the elderly,^{78,122} and physiologic variability is great. Alternative measurements, such as the Modification of Diet in Renal Disease (MDRD) Study Group equation, serum cystatin C, and others are also proposed, but no current method of estimating kidney function in the elderly appears to be superior for use in the clinical setting.^{125,136} For all of these reasons, it is difficult to accurately predict the renal elimination of xenobiotics or their metabolites in the elderly. A practical solution is to assume that kidney

function has declined significantly and to exercise caution when prescribing maintenance doses of drugs with a narrow therapeutic-to-toxic ratio (Table 33–3). Failure to do so is an important cause of toxicity.⁸⁷

TABLE 33–3. Xenobiotics with Narrow Therapeutic-to-Toxic Ratios and Potential for Accumulation in the Presence of Diminished Kidney Function

Antimicrobials
Aminoglycosides
Imipenem
Pyrazinamide
Vancomycin
Opioids with active metabolites that may cause toxicity
Morphine (morphine 6-glucuronide): respiratory depression; (morphine 3 glucuronide): neuroexcitation
Codeine (morphine)
Hydromorphone (hydromorphone 3-glucuronide): potential for neuroexcitation
Meperidine (normeperidine: neuroexcitation, seizures)
Dabigatran
Digoxin
Glyburide
Heparins (low-molecular-weight)
Lithium
Metformin
Nonsteroidal antiinflammatory drugs
Procainamide (N-acetyl procainamide)
Salicylates

The nature and degree of impact of age-related hepatic changes on drug elimination is controversial. Liver mass decreases with an associated decrease in hepatic blood flow,¹⁴⁶ which results in decreased efficiency of hepatic extraction. Enzymatic processes are often unpredictable,⁷⁷ and although hepatic oxidation appears to decline with age, this change is difficult to demonstrate. There is substantial genetic variability among cytochrome P450 isoenzymes, making it difficult to interpret studies of age-related alterations in oxidative metabolism. Some studies that consider cofactors that could affect hepatic enzymes, such as concurrent xenobiotics or cigarette smoking, or that determine isoenzyme genotype may demonstrate that there is no age-related change in hepatic oxidative enzyme function.¹⁰

Hepatic conjugation does not decline significantly with age, so xenobiotics such as temazepam and oxazepam that are metabolized by these processes do not have prolonged elimination half-lives. In contrast, xenobiotics such as diazepam and flurazepam, which are metabolized by hepatic oxidative enzymes, are eliminated more slowly with age.⁵³ Similar to many oxidized xenobiotics, metabolites of diazepam and flurazepam are active, undergo further metabolism, and remain in circulation after the parent xenobiotic has been metabolized. The active metabolites of some xenobiotics, such as opioids, are renally eliminated, and excretion may be prolonged because of an age-related decline in kidney function (Table 33–3).

Other changes in enzyme systems may occur late in life. For example, a decline in gastric alcohol dehydrogenase activity increases the bioavailability of ingested ethanol in the elderly.¹⁰⁸ The decline in this enzyme is attributed to the increased incidence of gastric atrophy with age. The etiology of the age-related gastric mucosal changes is uncertain, with the relative contributions of underlying *Helicobacter pylori* infection^{7,38} and antiparietal cell antibodies the subjects of research.¹⁵⁰ Whether age-related changes occur in metabolic enzymes that are present in the intestines, brain, kidneys, and

other organ systems and what impact such changes have on drug disposition and drug interactions are also likely to become active areas of research. Studies to date have not demonstrated a substantial effect of age on P-glycoprotein, a transmembrane transport protein involved in xenobiotic interactions in the kidneys, intestines, and other organs.¹¹

Age-related alterations in body composition may affect xenobiotic disposition in later life (Table 33–2). For example, lean muscle mass and total body water decline, and the fat-to-lean ratio increases with advancing age.^{81,103} Thus, highly lipid-soluble xenobiotics tend to have an increased volume of distribution (Vd). As a result, there may be a delay before steady state is reached, and peak effect and toxicity may occur later than expected as demonstrated with amiodarone and certain benzodiazepines. In contrast, xenobiotics that distribute in water, such as ethanol, have a smaller Vd, leading to higher peak concentrations, accounting at least in part for the more pronounced peak effect of ethanol in the elderly. This may also account for the increased BAC attained in an older adult who drinks an equivalent amount of alcohol as a younger person, as noted above.^{134,138}

Protein reserve diminishes with age as a consequence of decreased muscle mass and decreased protein synthesis.¹¹⁰ Although serum albumin concentration remains in the normal range in healthy elderly individuals,¹⁹ elderly people are more likely to experience a rapid decrease in albumin concentrations when experiencing acute or chronic illness or when their protein intake diminishes.^{34,148} A decline in serum protein concentration increases the free or active fraction of xenobiotics that are otherwise highly protein bound. Free xenobiotic is able to travel more readily to the liver and kidney for metabolism or excretion, so a gradual change in the serum protein concentration is unlikely to lead to a change in the patient's response to the xenobiotic. However, these changes may be clinically important for interpreting serum concentrations of highly protein-bound xenobiotics. Clinical laboratories typically measure total xenobiotic concentrations, which include both free and bound xenobiotic. Because most xenobiotic is bound, the reported value reflects mostly bound xenobiotic; therefore, the total xenobiotic concentration may be in the therapeutic range even though the active unbound fraction is actually elevated. Phenytoin, which is highly bound to albumin, serves as an illustrative example. If the serum concentration of phenytoin is reported as subtherapeutic, the physician might order a dose increase even though the free fraction of phenytoin actually is in the therapeutic range. With a dose increase, the free or active fraction may increase to toxic concentrations. Basic xenobiotics are not bound to albumin but to α -1-acid glycoprotein, an acute-phase reactant that tends to increase, rather than decrease, with age.¹ However, the increase attributed to age is most likely related to underlying disease. These unpredictable changes would be expected to have the reverse effect on the ratio of bound to unbound xenobiotic in any laboratory report. However, the correlation between clinical effect and free xenobiotic concentrations requires further study because there may be complex factors involved—for example, alterations in Vd, tissue-specific xenobiotic concentrations, and the contribution of other serum proteins to xenobiotic binding.

The precise contributions of age-related changes in the gastric and intestinal tract to toxicity have not been adequately determined. Changes in gastric absorption are not substantial enough to have an important clinical impact, and if anything, there is a modest decline, partly because of delayed gastric emptying, which could cause a delay in absorption of certain xenobiotics. However, age-associated changes in the gastric mucosa may account for enzymatic changes, as demonstrated in the case of alcohol dehydrogenase, noted above.

PHARMACODYNAMICS

Pharmacodynamic factors may also affect a patient's response to a particular xenobiotic. In general, age-related physiologic changes in target or non-target organs lead to increased sensitivity to most xenobiotics, although sensitivity to some xenobiotics may also be decreased. For example, there is evidence that the sensitivity of the β -adrenergic receptor declines with aging, leading to a diminished response to both β -adrenergic agonists and antagonists.^{31,43,139} However, these experimental findings may not necessarily be demonstrated clinically.^{5,6} Observed enhanced sensitivity to xenobiotics is probably due to altered pharmacokinetics in many, if not most, cases.⁵⁶ Proving that enhanced sensitivity is related to altered pharmacodynamics would require demonstrating that the concentration of drug at the tissue site was not increased as the result of diminished elimination. Regardless of the mechanism, it is important to recognize that the response to a given xenobiotic might be altered in specific ways among the elderly. These altered responses are probably caused less by chronologic aging and more by an increased prevalence of disease.^{28,56} Table 33–4 provides examples of pathologic or physiologic changes that frequently occur in the elderly and disorders that are worsened or unmasked by xenobiotics.

TABLE 33–4. Pathophysiologic Disorders Exacerbated or Unmasked by Xenobiotics in the Elderly^a

Disorder or Alteration	Drug	Possible Outcome
ADH secretion (increased)	Antipsychotics, SSRIs	Hyponatremia
Androgenic hormones (decreased in men)	Digoxin, spironolactone	Gynecomastia
Baroreceptor dysfunction, venous insufficiency	Antipsychotics, diuretics, TCAs, α_1 -adrenergic antagonists	Orthostatic hypotension
Bladder dysfunction	Diuretics, α_1 -adrenergic antagonists	Incontinence
Cardiac disease	Thiazolidinediones	Congestive heart failure
Dementia	Sedatives, anticholinergics, many others	Confusion
Gastritis (atrophic)	NSAIDs, salicylates	Gastric hemorrhage
Immobility, cathartic bowel	Anticholinergics, opioids, CCBs	Constipation; fecal impaction
Nodal disease (sinus or AV)	β -Adrenergic antagonists, digoxin, CCBs	Bradycardia
Parkinson disease; Lewy body dementia	Antipsychotics, metoprolol	Parkinsonism
Prostatic hyperplasia	Anticholinergics, TCAs, doxapramide	Urinary retention
Thermoregulation, disordered	Antipsychotics	Hypo- or hyperthermia
Venous insufficiency	CCBs, gabapentin	Edema

*Disorder may be preclinical.

ADH = antidiuretic hormone; AV = atrioventricular; CCB = calcium channel blocker; NSAID = nonsteroidal antiinflammatory drug; SSRI = serotonin reuptake inhibitor; TCA = tricyclic antidepressant.

UNINTENTIONAL POISONING, ADVERSE DRUG EVENTS, AND THERAPEUTIC ERRORS

Although the elderly account for numerically far fewer poisoning exposures overall, the exposure rate per 100,000 population remains substantial. The contribution of ADEs and therapeutic errors may pose a particular problem for older patients and have become an important part of poisoning exposure analysis in recent years.

The incidence of ADEs among adults increases steadily with age.¹⁵ An ADE is defined as “one that occurs with normal, prescribed, labeled or recommended use of the drug.”¹³ ADEs are more likely to be serious in the elderly than in younger adults. Serious ADEs are those resulting in death, hospitalization, life-threatening outcome, disability, or other serious outcome²³ and are most prevalent among people 85 years of age and older.¹⁸

Likewise, exposures in persons older than age 60 years are often the result of therapeutic errors.^{29,36,62} A therapeutic error is defined as “an unintentional deviation from a proper therapeutic regimen [of a medication or product used as a medication]⁶² that results in the wrong dose, incorrect route of administration, administration to the wrong person, or administration of the wrong substance;” therapeutic errors also include “unintentional administration of drugs or foods which are known to interact.”¹³ In the NEISS-CADES study, unintentional overdoses (defined as “excessive doses or supratherapeutic drug effects”) accounted for 65.7% of ADE-related hospitalizations in older adults.¹⁴ Risk factors for this age-related vulnerability include physiologic changes that affect xenobiotic disposition or effect, patient errors caused by cognitive or visual impairment, or lack of provider proficiency in geriatric prescribing principles.

In contrast to serious consequences of therapeutic errors or unintentional overdoses, serious reactions can occur with appropriate doses of certain medications. An important example is the neuroleptic malignant syndrome (NMS), which is potentially life threatening.²² Although one might predict it would be more common to occur in late life when abnormalities in thermoregulation are more common,¹² the risk of developing NMS has not been linked to advanced age per se.²² However, antipsychotic drugs are often prescribed to frail elderly, especially those with dementia, and NMS can be overlooked in a patient with comorbidities that could obscure a precise diagnosis. For example, NMS must be distinguished from such geriatric syndromes as cerebrovascular events, heat stroke, or neuroleptic sensitivity syndrome that occurs in Lewy body dementia.²²

Syndromes such as NMS are unpredictable and relatively rare at any age. Among elderly patients, serious or life-threatening ADEs are more typically caused by commonly prescribed drugs, such as anticoagulants, insulin, cardiovascular and insulin secretagogues and drugs that cause delirium, such as sedative-hypnotics, opioids, and anticholinergics (Table 33-1).

As many as 42% of serious ADEs reported in elderly patients are potentially preventable.^{8,57,58} NEISS-CADES data reveal that drugs requiring careful outpatient monitoring are disproportionately represented among ED visits attributed to unintentional drug overdose.^{14,16} Data from 2007 to 2009 indicate that warfarin, insulins, antiplatelet agents, and insulin secretagogues accounted for an estimated 67% of ADE-related hospitalizations in people 65 years of age and older, with digoxin and anticonvulsants contributing another 5.2%.¹⁶ The previously mentioned medications can be supervised with therapeutic as well as clinical monitoring. For certain other medications, ADEs are often best prevented by not prescribing them to vulnerable patients or by cautioning against their use if they are available without prescription. Criteria have been developed to guide clinicians regarding these “potentially inappropriate medications” (PIMs) in elderly patients.⁴ Xenobiotics deemed potentially inappropriate in the elderly have caused numerically fewer ADEs than more frequently prescribed xenobiotics,^{14,16,100} but consensus as well as evidence exist that they are strongly associated with adverse outcomes in elderly patients, including hospitalization and mortality.^{4,48,85} PIMs are also linked to enhanced risk of specific ADEs. For example, the elderly are at enhanced risk of severe upper gastrointestinal (GI) bleeding from NSAIDs.¹⁴⁵ Although this could be partly explained by increased exposure to and regular use of these drugs for chronic conditions, older adults may be more vulnerable to their effects because of underlying atrophic gastritis. The elderly are also at greater risk of prolonged hypoglycemia from certain sulfonylureas, particularly glyburide (glibenclamide).¹²⁰ Age-related mechanisms to explain this vulnerability to glyburide may include a decreased counterregulatory hormonal response to xenobiotic-induced hypoglycemia,⁹⁷ inappropriate stimulation of insulin if hypoglycemia is present,¹²⁹ or reduced excretion of a renally eliminated active metabolite of glyburide.⁷² Finally, as noted earlier, data gleaned from ED visits do not capture problems that occur and may or may not be managed in other settings. Other age-related factors involved in enhanced susceptibility to ADEs are given in [Tables 33–2 and 33–4](#).

ADVERSE DRUG EVENTS: RECOGNIZING RISK AND AVOIDING PITFALLS

A complicated medication regimen reduces adherence,⁹⁸ increases errors, and increases the risk of clinically important xenobiotic interactions. Geriatric patients take more prescription and nonprescription xenobiotics than any other patient group.⁷⁴ The likelihood of experiencing an ADE increases with the increasing number of xenobiotics taken.⁶⁵ The problem can be amplified by the common practice of pharmacies to fill an ongoing prescription of a particular medication with different brands over time; this diversity is expected but often problematic, and it is not necessarily accompanied by an adequate discussion with the patient or caregiver, or in the case of a mail order pharmacy, without highlighting the change. The new drug will differ in size, shape, or color from the medication previously dispensed, sometimes also appearing similar or identical to a different medication on the regimen, and medication errors can occur. The same problem can occur when a generic version of the prescribed medication replaces the drug with the “brand” name.

Concurrent disease in target or nontarget organs may alter the patient’s sensitivity to a xenobiotic, resulting in a serious ADE even when the patient is given a standard or previously used dose. Coexistent disease is often subclinical, and the patient’s enhanced sensitivity may not be anticipated. For example, a patient with subclinical Alzheimer disease whose cognitive function is overtly normal may acutely develop delirium or symptoms of dementia when given standard doses of drugs such as sedative–hypnotics or TCAs. Delirium is a medical emergency and an important cause of ED visits by the elderly.⁶⁷

Another factor contributing to ADEs is physician’s lack of knowledge with regard to the principles of geriatric prescribing.^{41,60,105} In addition to prescribing inappropriate doses or increasing the dose too rapidly, clinicians may prescribe drugs considered potentially inappropriate for the elderly at any dose, such as TCAs, anticholinergics, and long-acting benzodiazepines.⁴ At a minimum, and particularly in the case of potentially inappropriate medications, it is reasonable to attend to specific risk factors outlined here and elsewhere in an effort to prevent ADEs.

Another problem is that clinicians may be unduly ready to prescribe drugs recently on the market, despite availability of acceptable and often less expensive alternatives. Recently approved medications are sometimes promoted as being safer than older ones, but problems often become apparent only after marketing and use by large numbers of patients. For example, the hypnotic agent zolpidem was marketed as a safe alternative to benzodiazepines for the elderly. However, like benzodiazepines, zolpidem may cause confusion, global amnesia, memory loss, and falls.^{140,142} Low-molecular-weight heparins (LMWHs), such as enoxaparin and dalteparin, are other examples. LMWHs have more predictable pharmacokinetics than unfractionated heparin and are associated with a lower rate of overall bleeding. However, because therapeutic monitoring requires measurement of anti-factor Xa activity, which is not as readily available as standard tests such as activated partial thromboplastin time (aPTT), monitoring is usually not performed.⁶⁴ LMWHs such as enoxaparin and dalteparin are eliminated by the kidneys, and repeated doses lead to progressive increases in antifactor Xa activity when GFR is 30 mL/min or below,^{27,90} a degree of CKD that is common in frail elderly patients. Less severe levels of CKD may also result in reduced enoxaparin clearance that might be avoided with lowered doses.⁶⁶ Most reported cases of

serious, unexpected enoxaparin-induced bleeding occur in elderly patients who are receiving “standard,” not age-appropriate, dosing.^{96,135,137} Similar problems should be anticipated with other new anticoagulants. For example, the release of dabigatran, a renally eliminated direct thrombin inhibitor approved in 2010 for management of atrial fibrillation, was soon followed by many reports of severe GI bleeding and hemorrhagic stroke in the United States⁴⁴ and internationally.⁶³ The latter source specifically noted the preponderance of elderly patients in the reports. This finding is consistent with its use in atrial fibrillation, which is most prevalent among the elderly. Whether the risk of dabigatran is greater than that of warfarin is not known, because direct reports to the Food and Drug Administration (FDA) and others in the postmarketing period are not subject to comparison with other xenobiotics.¹²³ Likewise, it is premature to conclude that lack of monitoring or failure to adjust for occult CKD is a cause; however, the clinical trial supporting approval of dabigatran, which randomized subjects with mean age of 71 years, specifically excluded those with estimated GFR \leq 30 mL/min.³² Importantly, anticoagulants in general remain among the most important causes of ADEs, therapeutic errors, and hospitalizations.^{14,62} For elderly patients in particular, it is essential for clinicians to be mindful of the possible presence of occult CKD and lesions with the potential to bleed in order to reduce untoward bleeding in this high-risk group of patients.

It is not surprising that ADEs are first noted following drug approval in the postmarketing period when actual patients (as opposed to carefully selected research subjects) are exposed to the drug, because drugs and their effects are often inadequately studied in the elderly (Chap. 139).^{17,86} Reactions occurring in a small percentage of patients in a special subgroup can easily be missed during the initial drug evaluations. Even when a substantial number of subjects older than age 60 years are studied, a much smaller proportion of patients older than age 70 years may be included in clinical trials.⁸⁶ Thus, the adults at highest risk for many forms of toxicity are in a population that is often the least studied. Xenobiotic testing is typically carried out in subjects who are young adults and disease free, so pharmacokinetic profiles do not reflect patterns of xenobiotic disposition characteristic of geriatric patients. Pharmacokinetic testing may be limited to a one-time dose, and frequently the evaluation takes place over a short period of time. On average, approximately five half-lives of a xenobiotic are necessary to achieve steady-state xenobiotic concentrations (Chap. 9). Thus, a xenobiotic with a half-life of 24 hours might not reach a steady state for 5 days, and in the presence of prolonged elimination associated with age-related factors, a steady state might not be reached for substantially longer. As a result, even if elderly subjects are included in a drug trial, the ultimate effect might not be appreciated during testing intervals designed for younger patients.

Another factor is the nature of pharmaceutical research itself. Morbidity and mortality in elderly patients as a result of specific drugs might be avoided if the responsible drugs were studied under the predictably high-risk conditions typically present in the elderly. For example, xenobiotics eliminated by the kidney need to be evaluated after repeated dosing in elderly subjects. Gatifloxacin was removed from the market only after several years of use when it was finally linked to both hypoglycemia and hyperglycemia in large numbers of elderly subjects.^{55,106} Adverse events from xenobiotics that are studied in the elderly or others with chronic illness may be less obvious in the presence of comorbidity in the population at risk. The cyclooxygenase-2 (COX-2) inhibitor rofecoxib (Vioxx) was withdrawn from the market in 2004 after it was shown to increase the risk of myocardial infarction and stroke, especially in older adults.³⁹ Based on the complex actions of COX-1 and COX-2 in many tissues, the possibility existed that COX-2 inhibition might increase cardiovascular morbidity, for example, by leaving COX-1-mediated platelet aggregation unopposed while inhibiting prostacyclin-induced vasodilation or by leading to fluid retention and increased blood pressure via renal mechanisms.^{61,109} Because the elderly typically have one or more chronic illnesses²⁸ as well as occult disease, extra vigilance is required when new xenobiotics are given, and clinicians and clinical investigators must be very mindful of the theoretical possibilities of adverse outcomes. In view of the vulnerability of older patients to many medications, the FDA now requires that sponsors of new drug applications present effectiveness and safety data for important demographic subgroups, including the elderly, in their FDA submission data.²⁴ However, exceptions to the rule are allowed. For example, when studies have included insufficient numbers of subjects older than age 65 years to determine whether the elderly respond differently to the drug, the labeling must state this, but the statement is a poor substitute for providing actual efficacy and safety data.³⁰ Unfortunately, geriatric recommendations in the package insert may thus be insufficiently specific to provide guidance for drugs commonly used in this population.¹²⁶

Drugs, such as digoxin, warfarin, and diuretics, commonly prescribed in the elderly, are frequently involved in serious drug interactions. This situation is complicated by the frequency with which elderly patients, who often have multisystem disease, visit multiple physicians, who prescribe medications without specific knowledge of, or attention to, the remainder of the patient’s drug regimen, thereby increasing the risk of inappropriate combinations.^{52,132} Problems can also arise when patients obtain prescriptions from more than one pharmacy or mail order service. Warfarin is a particular problem, owing to its narrow therapeutic index and numerous pharmacokinetic as well as pharmacodynamic interactions, the potential for which (eg, with certain antibiotics) may often be ignored at the point of care.⁵⁰

Herbal preparations used by the elderly also may interact with prescription medications.⁷⁰ The use of herbal preparations has increased substantially in recent years, particularly in patients with illnesses such as cancer, dementia, and depression, which commonly affect the elderly. Very few patients voluntarily report use of these or other nonprescribed therapies to their physicians, and too often the physician fails to inquire specifically about such “alternative” or

“complementary” therapies. Poisonings, herb–drug interactions, and other problems related to herbal preparations are discussed further in [Chap. 45](#).

The use of nonprescription pharmaceuticals may also cause serious adverse effects. For example, excessive use of magnesium-containing preparations frequently causes severe toxicity in older individuals. Impaired GFR, decreased GI motility, and other medical comorbidities are just three risk factors that potentiate magnesium toxicity in the elderly. The source of magnesium in these cases may include the cathartics that contain magnesium hydroxide (Milk of Magnesia) and magnesium citrate, antacid preparations, and magnesium sulfate (Epsom salts).⁴⁹ Magnesium-containing laxatives are still sometimes used in hospital settings with serious outcomes.¹⁰⁴ Likewise, sodium phosphate formulations may harm kidney function in certain elderly patients despite normal baseline creatinine.⁷⁶ Virtually all of the most popular nonprescription medications⁷⁴ are more likely to produce problems in the elderly than in younger patients, including GI bleeding (aspirin and other NSAIDs), enhanced warfarin sensitivity (cimetidine), confusion and urinary retention (anticholinergic antihistamines), and cardiovascular symptoms (pseudoephedrine).

Outdated and discontinued xenobiotics are an additional problem for the elderly, who often retain unused or partially used products in their homes for decades or may continue to request prescription renewals when safer or more effective alternatives are available. Patients may be unwilling to change or physicians may continue to renew the prescription without sufficiently reevaluating the patient. Potential examples include digoxin and theophylline, which have been responsible for large numbers of adverse events diagnosed in EDs,^{14,15} as well as sedating antihistamines, other anticholinergics, and diazepam.

Other age-related factors may increase the risk of unintentional poisonings in geriatric patients; impaired vision, hearing, and memory may lead to misunderstanding or an inability to follow directions concerning the use of prescription and nonprescription drugs. Dementia is another important risk factor in unintentional poisonings. In addition to cognitive impairment, patients with dementia sometimes exhibit abnormal feeding behaviors, which may lead to ingestion of toxic xenobiotics.¹⁴³

MANAGEMENT

Management decisions must be made with the foregoing principles in mind. GI decontamination should proceed as in younger patients. However, because constipation is a more frequent problem in the elderly, when multiple-dose activated charcoal is used, particular attention must be paid to GI function and motility. The specific precautions and contraindications in the basic management and GI decontamination detailed in [Chap. 8](#) are particularly pertinent for the geriatric population.

The presence of clinical or preclinical congestive heart failure or CKD may increase the risk of fluid overload when sodium bicarbonate is used. In the elderly, extracorporeal removal may be indicated earlier in cases of salicylate, lithium, or metformin poisoning, in which elimination may be hampered by a decreased GFR.

A situation that may go unrecognized in geriatric patients is the problem of alcohol or other substance withdrawal syndromes. Because elderly patients are typically not perceived as substance abusers, or because a physician evaluating an unfamiliar patient may not be aware of the patient’s chronic use of prescribed benzodiazepines or opioids, the possibility of substance withdrawal may not be considered when unanticipated complications occur during hospitalization.

Strategies to limit unintentional toxic exposures in elderly patients with cognitive or sensory impairment should be similar to those used in young children, who are also at high risk of ingesting toxic substances or pharmaceuticals prescribed for others in the household. The strategies should include the removal of potentially dangerous and unnecessary xenobiotics from the patient’s environment. The physician should request that the patient or caregiver bring all medications to the office in the original bottles. The physician should then make an effort to limit the number of medications prescribed or to seek alternative medications with a safer therapeutic index or appropriate geriatric safety profile. Administration and control of the medications by directly observed therapy may, of necessity, become the responsibility of the caregiver rather than the patient.

CRITERIA FOR ADMISSION AND TIMING OF DISCHARGE

When geriatric patients are evaluated in the ED for poisonings or serious ADEs, the need for hospital admission should be weighed carefully against the known hazards of hospitalization for the elderly.³⁵ The physician should be particularly alert to certain situations that might mandate admission, including unexplained mental status changes, overdose of a prescribed medication with a prolonged duration of action, or evidence of inadequate home care or elder abuse/neglect, such as poor hygiene or unexplained injury.

When there is concern that the established caregivers at home may be abusing or neglecting the patient, the patient requires further observation, removal from the environment, and possibly hospitalization. Signs of actual physical abuse may be more obvious than signs of neglect.⁸² Vulnerable elderly who are physically disabled or cognitively impaired may

be brought to the hospital because of presumed illness, but the source of the problem may actually be the caregiver. The caregiver, frequently but not necessarily a family member, may be depleting the patient's funds for personal use. Patients may become ill because funds were diverted from the purchase of food or because the patient's prescription drugs were sold on the street. More direct abuse may take the form of intentional poisoning or oversedation of the patient by overdose of the patient's own prescription drugs, or selling the patient's medications (diversion), resulting in clinical deterioration. Provision for follow-up care, such as an alternative place to live and guardian appointment, is essential because abuse and neglect are associated with serious outcomes.⁸³

Unresolved mental status changes may require close observation and hospitalization. Elderly patients who are confused or unable to walk are sometimes mistakenly assumed to be chronically impaired. However, incomplete explanation of an altered mental status or physical impairment should prompt careful inquiry into the patient's baseline functional status. Poor function should never be assumed to be "normal aging." Many very elderly patients are cognitively normal, physically robust, and independent in all activities of daily living.

A patient whose problem has been attributed to overdose with or accumulation of a long-acting medication requires careful monitoring. Because the durations of action may be markedly prolonged among geriatric patients, a higher degree of vigilance is required. An important example is chlordiazepoxide, which is commonly used for alcohol withdrawal and exhibits very long half-life in older patients, especially after repeated dosing. The ultra-long-acting sulfonylurea chlorpropamide is rarely used today, but glyburide may cause relatively prolonged hypoglycemia compared with other insulin secretagogues, as noted above.

SUMMARY

- Older patients may account for only a small fraction of total poisoning victims, but when poisoned, they have a high mortality rate.
- The elderly are much more likely to experience serious ADEs as a consequence of both appropriate and inappropriate use of medications.
- Attention to risk factors is essential in this vulnerable population.
- Important risk factors include pharmacokinetic and pharmacodynamic changes; the presence of overt or subclinical disease, including dementia; patient and provider error; suicide risk; complex therapeutic drug regimens; and a general lack of knowledge about the principles of prescribing for the geriatric population.

34 POSTMORTEM TOXICOLOGY

Rama B. Rao and Mark A. Flomenbaum

Postmortem toxicology is the study of the identification, distribution, and quantification of xenobiotics after death. This information is used to account for physiologic effects of a xenobiotic at the time of death through its quantification and possible redistribution in the body at the time of autopsy. Several variables may cause changes in xenobiotic concentrations during the interval between (1) the time of death and subsequent autopsy and (2) the storage interval between the time of sampling and the time of testing. Toxicologists and forensic pathologists are frequently asked to interpret postmortem xenobiotic concentrations and decide whether the reported values are meaningful and whether these xenobiotics were incidental or contributory to the cause of death.

The development of the field of forensic toxicology and the improvement of laboratory technology now permit more refined identification and quantification of xenobiotics. The interpretation of postmortem xenobiotic concentrations and their significance, however, continues to evolve.

This chapter reviews factors that affect xenobiotic concentrations identified at autopsy and discusses an approach for interpreting postmortem toxicologic reports as they relate to the cause and manner of death.^{38,41,43,49–51,59,69,79,97}

HISTORY AND ROLE OF MEDICAL EXAMINERS

The relationship between antemortem xenobiotic exposures and death has been a subject of investigation for centuries. In 12th-century England, an appointee of the royal court, eventually named the coroner, was designated to record and identify causes of death.⁷³ In suspicious circumstances, coroners investigated poisonings, but scientific methods were primitive, and conclusions regarding such deaths were conjecture at best.

By the mid-19th century, however, techniques for detecting certain xenobiotics in postmortem tissue were developed and focused generally on identifying heavy metals as a cause of death in homicides.^{44,73,77,94,99} At that time, coroners were still elected or appointed individuals with little or no medical training. However, with better laboratory techniques and autopsies being performed by trained pathologists, the specialty of forensic medicine continued to develop. In late 19th-century Massachusetts, trained pathologists, referred to as medical examiners, ultimately replaced the coroner system and were eventually empowered by the state to investigate certain types of unusual or suspicious deaths (medicolegal autopsies).⁷³ Currently in the United States, legal jurisdiction of death investigations is the responsibility of either a coroner or a medical examiner depending upon the state or county, with 19 states using medical examiner systems almost exclusively.⁴⁸

The medicolegal autopsy, ideally, is performed by a forensic pathologist who attempts to establish the cause and manner of death (Table 34–1). The cause of death is the etiology ultimately responsible for death to occur. For example, the presence of cyanide in the toxicologic evaluation may be sufficient to establish cardiorespiratory arrest from cyanide poisoning. The manner of death is an explanation of how the death occurred, or the circumstances surrounding the terminal events. It broadly distinguishes natural from nonnatural (or violent) deaths. Nonnatural deaths, depending on the jurisdiction, may be divided into several categories (Table 34–2). With the identification of cyanide, the manner of death cannot be considered natural because a poisoning is a “chemically traumatic” (violent) event. The medical examiner must make the best determination of the manner of death based on the available evidence.^{99,106} An unintentional exposure may be classified as an accident (a legal term for some unintentional nonnatural deaths), and intentional self-injury may be classified as a suicide. If the circumstances indicate an exposure due to the acts of another person, the manner of death is classified as a homicide.

TABLE 34–1. Information Used by Forensic Pathologists

Autopsy

Evidence from the crime scene

Laboratory investigations

TABLE 34–2. Categories of Manner of Death

- Natural
- Nonnatural
- Homicide
- Suicide
- Accident
- Therapeutic complication^a
- Undetermined

^aNot all jurisdictions recognize therapeutic complication as a manner of death.

Determination of the manner of death has important consequences. Homicide necessitates involvement of law enforcement officials for further investigation. Cases deemed suicide not only impact survivors psychologically but also may nullify some life insurance payments. Conversely, a case deemed an “accident” may have a double-indemnity insurance clause. Assignment of financial responsibility for workplace deaths may be similarly affected when xenobiotics are identified in the postmortem specimens of involved workers.

Recognition of xenobiotic-related deaths also has significant public health consequences. The forensic pathologist may be the first to identify and report critical information regarding fatal drug reactions, medication errors, rapidly fatal epidemics associated with illicit xenobiotic use or malicious intent activities. In cases of occupational and environmental xenobiotic-related fatalities, interventions can be implemented to prevent subsequent morbidity and mortality. In addition, the pathologist describes gross and microscopic autopsy findings that may elucidate mechanisms of xenobiotic toxicity.

Postmortem toxicologic techniques may be used in other types of investigations as well. For example, when carboxyhemoglobin is identified in burned human remains from an airplane crash, a cabin fire before descent is more probable than deaths due to a fire on impact. This type of postmortem analysis is useful in the reconstruction of events leading to the crash.^{8,55,64,98}

THE TOXICOLOGIC INVESTIGATION

Ordinarily, toxicologic samples are collected as part of a complete autopsy. In the hospital, when a death is assumed to be from natural causes, the hospital pathologist may perform an autopsy with the consent of the family. In a medicolegal investigation, however, the forensic pathologist determines the need for a complete or partial autopsy and has statutory authority to act on that determination independent of familial consent. Occasionally, only fluid samples may need to be obtained along with an external inspection of the body if a complete autopsy is either unnecessary or the family has legal or religious grounds for objection. The precise list of xenobiotics screened in postmortem samples varies greatly by jurisdiction. Investigations in large cities may routinely screen for hundreds of illicit, therapeutic, and environmental xenobiotics. Occasionally, the suspicions of the medical examiner or death scene investigator warrant special assays that are performed only upon request.

The sampling of fluid and tissue may be obtained minutes to years after death. The postmortem interval, defined by the time between death and autopsy, is important, but many other factors will define the extent of bodily decomposition. This is dependent on environmental conditions such as ambient temperature, humidity, aerobic versus anaerobic surroundings, and immersion in water.⁶⁵ Samples may be collected from a body during advanced stages of decomposition, after exhumation from graves, or even after embalming.^{8,37,38,45,62,78} Knowing the condition of the body at the time of sampling assists in interpreting the toxicologic findings. These postmortem changes are reviewed below.

DECOMPOSITION AND POSTMORTEM BIOCHEMICAL CHANGES

The first stage of decomposition is autolysis, during which endogenous enzymes are released and normal mechanisms maintaining cellular integrity fail.⁵⁸ Chemicals move across compromised and leaky cellular membranes down relative concentration gradients. Glycolysis continues in the red blood cells until intracellular glucose is depleted, and then lactate is produced. Ultimately, intracellular ions and proteins are released into the blood, and tissue and blood acidemia develops leading to the biochemical changes described in Table 34–3.⁹⁹

TABLE 34–3. Postmortem Biochemical Changes over the First 3 Days^a

Increased	Decreased	Stable	Variable
Amino acids	Cl ⁻	BUN/Cr (vitreous)	Lipids
Ammonia	Glucose	Cholinesterases	T ₃
Ca ²⁺ , K ⁺ , Mg ²⁺	Na ⁺	Cortisol (serum)	
Epinephrine	pH	Proteins (serum)	
Hepatic enzymes	T ₄	Sulfates	
Insulin (especially right heart blood)			

^aIn refrigerated bodies.

BUN = blood urea nitrogen; Cr = creatinine; T₃ = triiodothyronine; T₄ = thyroxine.

The next stage of decomposition in most normal environments is putrefaction. This stage involves digestion of tissue by bacterial organisms, which typically colonize the bowel or respiratory system. Later, additional organisms may be introduced by insects or other external sources. As the putrefactive process advances, the colors of the skin and organs change; epithelial blebs may form and separate from the underlying dermis; and gases may accumulate, resulting in foul odors and bloating.⁹⁹

If death occurs in a very warm, dry climate, such as a desert or comparably arid environment, the body may desiccate so rapidly that putrefactive changes may not occur. This results in mummification and produces a lightweight cadaver with a tight, dry skin enveloping a prominent bony skeleton.⁹⁹

If the environment is very cold and devoid of oxygen, such as at great depths under water, putrefaction will be slowed. Anoxic decomposition of fatty tissues occurs, forming a white, cheesy material known as adipocere.

Another phase of decomposition, anthropophagia, occurs in unprotected environments where insects or other animals feed on the remains.⁹⁹

Because most postmortem changes are derived by chemical reactions and are temperature dependent, with increased temperatures accelerating the process and cooler temperatures retarding it. In general, morgue refrigerators achieve low enough temperatures (40°F {4°C}) to prevent further gross decomposition and many associated postmortem changes.

Another process that alters natural decomposition is embalming, a process of chemically preserving tissues that may be performed in a variety of ways.^{46,47} Typically, blood is drained through large vessel pumps, and an embalming fluid is injected intravascularly to perfuse and preserve the face or other tissues. Intracavitary spaces may be injected with the preserving substances, and solid organs may or may not be removed.

SAMPLES USED FOR TOXICOLOGIC ANALYSIS

Unless the medical examiner is suspicious about a death, only standard autopsy samples will be available in an otherwise intact body.^{24,38,53,60,82,97} These typically include samples of blood, gastric contents, bile, urine, and occasionally solid organs such as the liver or brain. Less commonly, vitreous humor is obtained for analysis (Table 34–4). If the decedent was hospitalized before death, antemortem specimens may also be available for evaluation and comparison. These specimen analyses are reviewed in greater detail below.

TABLE 34–4. Sampling Sites^{16,21,25,37,51,92}

<i>Routine</i>	<i>Infrequent</i>	<i>Uncommon</i>
Bile	Antemortem blood	Casket fluid
Blood	Cerebrospinal fluid	Extravasated fluid
Brain	Fat	Extravasated blood
Gastric contents	Hair	Insect larvae
Liver	Kidneys	Pupae casings
Vitreous humor	Muscle	
	Nails, skin	

Blood

Postmortem cell lysis limits the concept of plasma concentrations, and “blood” concentrations are reported instead. Most commonly a single site such as femoral or subclavian blood is usually sampled unless an unusual xenobiotic with nonuniform distribution is suspected of causing the death. In patients with a prolonged postmortem interval and in cases where intravascular blood is coagulated, right heart blood may serve as an alternative sample site.

Other sources of blood may sometimes be available to the forensic pathologist. These frequently include antemortem samples and occasionally extravasated blood, which is unlikely to undergo extensive metabolism. Intracranial clots, in particular, serve as useful comparative samples in patients with a prolonged survival period after exposure to a xenobiotic.⁶⁶

In advanced states of decomposition, blood from the abdominal or thoracic cavities is less useful because it may be contaminated by bacteria or other substances that may affect xenobiotic recovery or analysis.

Vitreous Humor

Because of the relatively avascular and acellular nature of the fluid, the vitreous humor is well protected from the early decompositional changes that typically occur in blood.^{16,19–21,25} When bodies are immediately refrigerated, creatinine, blood urea nitrogen, and sodium can be reliably approximated from vitreous humor samples for up to 3 or 4 days. Potassium concentrations are less reliable because cell lysis causes intracellular release. When vitreous glucose is elevated, hyperglycemia at the time of death can be assumed. A low vitreous glucose concentration, however, is a less reliable indicator of the antemortem serum glucose concentration, because a low vitreous glucose concentration may be attributable to either antemortem hypoglycemia or postmortem glycolysis even in the relatively avascular vitreous.

The aqueous content of the vitreous is normally higher than that of blood and may affect the partitioning of certain water-soluble xenobiotics, such as ethanol.

Urine

Urine may be available during the autopsy and may reveal renally eliminated substances or their metabolites. Because the bladder serves as a reservoir in which metabolism is unlikely to occur, the concentrations of xenobiotics obtained during the autopsy reflect antemortem urine concentrations. An isolated urine sample is of limited quantitative value but may be useful when compared with other sample sites.

Gastric Contents

The gross contents of the stomach are inspected for color, odor, and the presence or absence of pill fragments, food particles, activated charcoal, and other foreign materials.⁹⁷ Typically, gastric concentrations of xenobiotics are reported as milligrams of substance per gram of total gastric contents. Xenobiotic-induced pylorospasm, diminished intestinal motility, or decreased splanchnic blood flow may all decrease gastric emptying and affect the quantitative values obtained from sampling different parts of the gastrointestinal tract.

Solid Organs and Other Sources

Xenobiotic concentrations in solid organs, such as the liver and brain, are usually reported as milligrams of substance per kilogram of tissue. Other tissue samples, including hair and nails, are used for thiol-avid xenobiotics such as metals. Rarely, tracheal aspirates of gases may be analyzed to confirm inhalational exposures. Pleural fluid analysis of postmortem xenobiotics typically yields qualitative results in decomposed bodies because redistribution of xenobiotics from the stomach and intestines may occur.^{32,89}

OTHER SAMPLING SOURCES

In an embalmed body, either the organs or tissues that remain relatively unembalmed, such as deep leg muscle,⁶⁸ or the embalming fluid itself may be used for analysis. Some authorities regulate the contents of embalming fluid specifically to avoid confounding postmortem analysis. Most embalming fluid in the United States consists of formaldehyde, sodium borate, sodium nitrate, glycerin, and water. When a body is disinterred, soil samples are usually obtained from above and below the coffin to permit identification of xenobiotics that may have leached into or out from the body.⁷⁸

On rare occasions, cremated remains, often referred to as cremains, are the only source of sampling available. Most metallic implants, such as pacemakers, are removed before cremation, and only dental remains, particulate matter, and occasionally calcified blood vessels are available for analysis.^{3,105} In most cremations performed in the United States, the incineration process is followed by mechanical grinding to yield a fine particulate matter.¹⁰⁵ The ability to extract xenobiotics from cremains is markedly limited at best, and little published data are available on the subject. A new technique to identify heavy metals such as lead from cremains has been described, but is not routinely used at present.^{3,105}

ENTOMOTOXICOLOGY

A variety of other anthropophagic insect species may demonstrate the presence of xenobiotics.^{1,42,62,63} This process of analysis is termed entomotoxicology. In putrefied bodies or bodies that have undergone anthropophagy, fluids and even insect parts can be analyzed. Forensic entomologists can collect samples of these insects from the remains. After taking into account the stage of insect life, environmental conditions, and the season, the approximate time of death can be extrapolated. The species Calliphoridae, or the bluebottle fly, is attracted to unprotected remains by a very fine scent that develops in the cadaver within hours of death. The adult fly lays eggs on mucosal surfaces or in open wounds. After the eggs hatch, the larvae feed on the decomposing tissue. Larval samples can then be examined for the presence of xenobiotics. To achieve accurate analysis, these samples must be preserved immediately after collection because living larvae can continue to metabolize certain xenobiotics. In another phase of their life cycle, the larvae undergo pupation, secreting a substance that encloses them into pupal casings until they hatch as adults. These pupal casings are often found in the soil beneath the body. Some xenobiotics have been identified in the casings long after the adult fly has emerged⁸⁴ (Table 34–5).

INTERPRETATION OF POSTMORTEM TOXICOLOGY RESULTS

After fluid and tissue samples have been collected and analyzed for the presence of xenobiotics, the process of interpreting these results begins. This complex task attempts to account for the clinical effects of a xenobiotic at the time of death by integrating medical history, autopsy, death-scene findings, and toxicologic reports. Multiple confounding variables may affect the sample concentrations of xenobiotics from the time of death to the time of testing after the autopsy. Variables include the nature, metabolism, and distribution of the xenobiotic; the state of health of the decedent prior to death; physical

and environmental variables during the postmortem interval; the techniques of analysis; and other findings of the autopsy (Tables 34–6 and 34–7).

TABLE 34–6. Considerations in Interpreting Postmortem Xenobiotic Concentrations

<i>Xenobiotic Dependent</i>	<i>Decedent Dependent</i>	<i>Autopsy Dependent</i>	<i>Other</i>
Pharmacokinetic considerations	Comorbid conditions	Handling and preservation	Laboratory techniques
State of absorption or distribution at time of death	Tolerance	Postmortem interval: State of preservation or decomposition	Evidence at scene
Postmortem redistribution	Pharmacogenetic variability	Sample sites	Previously published tissue concentrations
Postmortem metabolism		Specimens sampled	
Pharmacodynamic considerations			
Expected clinical effects			
Synergistic interactions			
Postmortem xenobiotic stability during			
Putrefaction			
Preservation

Trifluoperazine

Variables Relating to the Xenobiotic

Postmortem Redistribution. The xenobiotic concentration in blood may be higher during the time of sampling at autopsy than at the actual time death occurred if significant postmortem redistribution occurs.^{54,81,104–111} Redistribution typically occurs with xenobiotics that have large volumes of distribution and when decomposition results in release of intracellular xenobiotic into the extracellular compartment.⁸⁶ For example, amitriptyline may be released from tissue stores into the blood as autolysis progresses, resulting in a significantly higher blood concentration during the autopsy than at the time of death. If postmortem redistribution is not considered, xenobiotic concentrations obtained during the autopsy may be misinterpreted as being supratherapeutic or even toxic, and the cause of death may be inappropriately attributed to this xenobiotic.

Postmortem Metabolism. Less commonly, xenobiotic concentration may decrease secondary to postmortem metabolism. For example, cocaine continues to be degraded after death by endogenous enzymes such as cholinesterases in the blood, which continue to function in postmortem tissue and in vitro. Unless blood is collected immediately after death and placed in tubes containing enzyme inhibitors such as sodium fluoride, the concentration of cocaine will continue to decrease, and the analysis will not accurately reflect the concentration of the drug at the time of death.^{59,71,98,102} All available information regarding postmortem redistribution or metabolism of a specific xenobiotic must be considered for the proper interpretation

of the toxicologic results.

State of Absorption and Distribution. Both in the living and deceased, the state of absorption, distribution, and other toxicokinetic principles affect the apparent concentration of a sampled xenobiotic. For a xenobiotic with minimal postmortem metabolism or redistribution, the phase of absorption is suggested by the relative quantity of the xenobiotic in different fluids and solid organs. For example, a high concentration of xenobiotic in the gastric contents, with progressively lower concentrations in the liver, blood, vitreous, and brain, suggests an early phase of absorption at the time of death. When a xenobiotic is orally administered and the tissue concentration is highest in the liver, the relationship suggests a postabsorption phase but a predistribution concentration. A concentration found to be highest in the urine suggests that the xenobiotic was in an elimination phase at the time of death. Although this approach has limitations, it may be important for correlating the state of absorption and the expected clinical course of the xenobiotic. Unfortunately, multiple samples may not always be available at the time of autopsy or the interpretation of reports, and opportunities for subsequent sampling are often limited.

Xenobiotic Stability. Xenobiotic stability refers to the ability of a xenobiotic to maintain its molecular integrity despite postmortem changes such as decomposition of the body, adverse storage conditions, or the lack of preservatives.^{5,13,15,56,57,62,92,100,107,109,110} Postmortem xenobiotic stability was assessed in homogenized liver tissue infused with various concentrations of xenobiotics.¹⁰⁰ The samples were allowed to putrefy outdoors, and sequential sampling of xenobiotic concentrations was performed. The xenobiotics that decreased in concentration as putrefaction progressed were considered labile, and samples with a constant concentration were considered stable. The authors proposed that the chemical characteristics of a xenobiotic determine its stability. For example, labile xenobiotics share the molecular configuration of an oxygen–nitrogen bond, thiono groups, or aminophenols. Conversely, chemical structures that enhance stability include single-bonded sulfur groups, carbon–oxygen and carbon–nitrogen bonds, and sulfur–oxygen and hydrogen–nitrogen bonds. Although not explicitly studied in otherwise intact but putrefying bodies, logically, a less stable xenobiotic may be recovered in a lower concentration than the actual concentration at the time of death. This must be considered when information regarding stability is available and the body of a decedent is in an advanced stage of decomposition.

Xenobiotic Chemical Interactions. An artifact may result from a chemical interaction with a xenobiotic added during the postmortem interval, such as embalming fluid.³⁹ In a study of xenobiotic-spiked blood and formalin in test tubes, amitriptyline was formed by the methylation of nortriptyline.^{27,110} Identification of amitriptyline, which was not present at the time of death, could confuse the interpretation of toxicologic analyses.

Expected Clinical Effects of the Xenobiotic. For a fatality to be attributed to a xenobiotic, the expected clinical course from the exposure should be consistent with the autopsy findings. For example, what are the implications of a person found dead minutes after having been seen ingesting pills, if a large concentration of acetaminophen (APAP) is identified in both the gastric contents and blood but not in other tissues at autopsy?⁹¹ Although suicidal intent may be supported by this finding, the onset of death within minutes is inconsistent with a fatality due to an APAP overdose. Thus, another cause of death must be sought. Interpretation of postmortem toxicology must also incorporate clinically relevant consequences of xenobiotic interactions. For example, the combined ingestion of phenobarbital and ethanol can cause fatal respiratory depression. Although neither may be fatal alone, their additive effects must be acknowledged during toxicological interpretation.

Variables Related to the Decedent

Comorbid Conditions. The clinical response to a xenobiotic may be affected by acquired and inherited physiologic conditions that are not always identified or identifiable on autopsy. A thorough medical history is important and may assist in interpreting the clinical effects of a xenobiotic exposure. Similarly, certain clinical conditions may produce substances that interfere with postmortem laboratory assays. For example, an individual with a critical illness may produce digoxinlike immunoreactive substances (DLIS), which may cross-react with the postmortem digoxin assay.⁶ Without knowledge of DLIS production, the results may confound toxicologic analysis ([Chap. 65](#)).

Tolerance. Tolerance is an acquired condition in which increasingly higher xenobiotic concentrations are required to produce a given clinical effect. It is an important consideration for deaths in the presence of opioids, ethanol, and sedative–hypnotics. For example, respiratory depression and death from methadone may be easily diagnosed in an opioid-naïve individual with a history of methadone exposure and methadone-positive postmortem samples. However, the same methadone concentrations in a patient on chronic methadone maintenance therapy will not produce the same outcome. Unfortunately, no autopsy markers are available to indicate tolerance, and no biochemical or histologic markers are available during autopsy that may be used to predict clinically dangerous xenobiotic concentrations in a tolerant individual.²⁸ Complex postmortem assays analyzing opioid receptors are not routinely used.³⁶ Postmortem assessment of tolerance ultimately depends on knowledge of the patient, pharmacokinetics of the xenobiotic, and the best judgment of the investigator.

Pharmacogenetics. There is genetic variability in the expression of certain metabolic enzymes. For example, pharmacogenetic differences in metabolic enzymes, such as CYP2D6, predispose some individuals to fatal hypotension

from an inability to metabolize debrisoquine.

Similarly, deaths in young children have been reported from the use of therapeutic codeine. Postmortem blood analysis may reveal an elevated concentration of morphine, the codeine metabolite, and raise suspicion for a malicious overdose. Postmortem genotyping may provide an alternate explanation. Individuals with duplicate alleles for CYP2D6 may be ultrarapid metabolizers of codeine, rendering them susceptible to morphine toxicity despite generally acceptable dosing of codeine. Such distinctions are not routinely identifiable on autopsy.^{17,29,30}

Variables Relating to the Autopsy

State of Decomposition. In decedents in advanced stages of decomposition, xenobiotics may diffuse from depot compartments such as the stomach or bladder into adjacent tissues and blood vessels and secondarily affect their sample concentrations.^{23,38,66,76–78,85–87}

During putrefaction, bacteria cause fermentation of endogenous carbohydrates, resulting in ethanol formation. In decedents without gross evidence of putrefaction, especially those in cool, dry environments, endogenous ethanol production is minimal.^{18,22} With a longer postmortem interval or in an environment that is more conducive to ethanol production, the distinction between endogenous and exogenous sources of ethanol becomes more difficult. Sampling from multiple sites is often useful in making the distinction.¹⁰¹ A comprehensive review of interpreting postmortem ethanol concentrations is available elsewhere.⁶⁶

Handling of the Body or Samples. Inappropriate handling of the body may result in artifacts.^{91,93} In one reported case, methanol was detected in the vitreous humor of a decedent after embalming.¹² The methanol was subsequently traced to a spray cleanser that likely settled on the surface of open eyes during washing of the body.

In addition, inappropriate handling of samples may affect xenobiotic concentrations. In one study, autopsy blood was obtained from a diabetic man who died of bronchopneumonia. The samples were stored at 40°F (4°C) and tested at 2 and 5 days postmortem. The blood ethanol increased from 0.4 to 3.5 g/L because of an inadequate addition of fluoride preservative to the samples. The combination of inadequate preservation, hyperglycemia (vitreous glucose of 996 mg/dL), and bacterial sepsis created an ideal environment for ethanol production via fermentation.⁶⁶

In the United States, preservatives containing metals are currently banned for use in embalming because they may contaminate subsequent evaluation for metal poisoning. Formalin may also affect stability or quantitative identification of some xenobiotics. When necessary, an analysis of embalming fluid used by the mortician or soil sampling around disinterred bodies may facilitate the toxicologic investigation.^{19,34,107,109,110}

Autopsy Findings. In many xenobiotic-related deaths, the anatomic findings are nonspecific.¹⁰⁸ In some cases, the autopsy reveals confirmatory or supportive findings. A large quantity of undigested pills in the stomach is consistent with an intentional overdose, and suicide should be considered. Centrilobular hepatic necrosis may be found in decedents with a history of APAP overdose. The autopsy may also reveal other findings such as coronary artery narrowing, chronic hypertension, renal abnormalities, or a clinically silent myocardial injury. Such information may be useful to assess the potential effects of a xenobiotic in a patient with previously undiagnosed conditions. In other cases, the absence of a chronic condition may be strongly suggestive of a xenobiotic-related death. For example, a decedent with an autopsy finding of aortic dissection in the absence of chronic hypertensive findings or other predisposing conditions may suggest a xenobiotic-induced hypertensive crisis as may occur from use of cocaine or other sympathomimetics.

Artifacts Related to Sampling Sites. Site-specific differences in postmortem xenobiotic blood concentrations are common.³⁵ For example, blood obtained from femoral vessels may have low glucose concentrations because of postmortem glycolysis, but the blood glucose concentration removed from the right heart chambers may be high as a result of perimortem release of liver glycogen stores. As noted above, hyperglycemic conditions are more reliably assessed from sampling the vitreous humor as vitreous is a relatively protected environment in the early postmortem interval. An elevated vitreous glucose concentration suggests antemortem hyperglycemia. The individual interpreting the toxicologic report must know the exact site from which the sample was taken.^{20,60}

Ideally, samples from more than one site would be available for comparison; unfortunately, multiple blood samples are not often routinely obtained. Comparison of concentrations from different sites may reveal important information regarding the extent of xenobiotic absorption at the time of death and acute versus chronic exposure.^{9–11,20,26,30,52,67,72,80,82,85,88–90,95,96,101,103}

Other Considerations. Published therapeutic, toxic, and fatal postmortem xenobiotic concentrations are available to aid in the interpretation of postmortem specimens.^{4,70} However, the conditions associated with reported concentrations do not necessarily permit comparisons with the concentrations of the particular case under investigation. Thus, these resources are valuable but should be used mainly as representative of prior attempts at rigorous analysis and not accepted as absolute values that define either toxic or therapeutic concentrations. Similarly, formulas available for assessing xenobiotic doses or concentrations in the living are not usually applicable when analyzing postmortem samples.

Other Limitations

Although there are generalized standards of practice in forensic investigations, specimen collection and laboratory methodologies may vary.^{2,4} Some xenobiotic concentrations may be falsely elevated or depressed depending on the chosen methodology.^{32,72} Descriptions of specific toxicology laboratory techniques are beyond the scope of this chapter, but these variables must also be given consideration in the interpretations of results. Other limitations may include a lack of information relating to the circumstances of death and possible compromises in specimen handling because of the required protocols for the maintenance of proper chain of custody often of paramount importance in forensic autopsies.^{37,38}

SUMMARY

- Accurate interpretation of postmortem toxicologic reports requires an understanding of potential biochemical changes and other artifacts that affect postmortem testing.
- It is exceptionally difficult to absolutely correlate postmortem xenobiotic blood and tissue concentrations to those at the actual time of death.
- Postmortem toxicology is an evolving discipline that may permit only the most likely cause and manner of xenobiotic-related death to be identified.
- Progress in this field will depend on the continued collaboration between the treating physicians, medical and forensic toxicologists, and forensic pathologists.

SC2 SPECIAL CONSIDERATIONS

Organ Procurement from Poisoned Patients

Rama B. Rao

Xenobiotics can cause brain death due to the unique vulnerabilities of the central nervous system. With supportive care, however, such patients may be suitable candidates for organ donation.^{9,10,31,38} Early identification of potential donors is critical because the viability of transplantable tissue diminishes as duration from the time of brain or cardiac death prolongs.^{26,38} Timely identification may be further complicated by the presence of xenobiotics that mimic brain death.^{4,10,36}

A variety of protocols to establish brain death are reviewed elsewhere.^{4,10,36} Once brain death is established, organ procurement personnel assist in obtaining familial consent, deciding which organs are most suitable for transplant, and maximizing physiological support and perfusion until organ procurement occurs.³⁸ The protocols following controlled or uncontrolled donation after cardiac arrest are socially complicated and practiced extensively in Europe.³⁵

Successful transplantation of organs is reported from poisoned donors associated with a variety of xenobiotics^{1,2,5,7,9,10,12,16,25,29,30-34,37} (Tables SC2–1 and SC2–2). Although some xenobiotics are highly toxic, such as cyanide and carbon monoxide (CO), transfer of clinical poisoning to the organ recipient is not reported. This is likely caused by several factors, including xenobiotic metabolism, tissue redistribution or binding prior to procurement, as well as the means of handling organs during the transplantation process. For example, some xenobiotic clearance may occur in the myocardium during organ rinsing and cardiopulmonary bypass.²⁹ Furthermore, individual organs may not uniformly manifest toxicity in response to xenobiotic insults. For example, the heart of a CO poisoned donor was examined after a transplantation failed for technical reasons. The myocardium did not demonstrate histological signs of CO poisoning.³⁴ A comprehensive review with organ-specific procurement recommendations post–carbon monoxide poisoning is presented elsewhere.³

TABLE SC2–1. Organs Transplanted after Donor Poisonings

<i>Organ</i>	<i>Xenobiotics Identified in Donors</i>
Cornea ^{a,1,23,25,26,29}	Brodifacoum, cyanide
Heart ^{8,14,25,28,30}	Acetaminophen, β -adrenergic antagonists, alkylphosphate, benzodiazepines, brodifacoum, carbamazepine, carbon monoxide, chlormethiazole, cyanide, digitalis, digoxin, ethanol, glibenclamide, insulin, meprobamate, methanol, propoxyphene, thiocyanate
Kidney ^{a,2,4,6,10,25,26,29}	Acetaminophen, brodifacoum, carbon monoxide, <i>Conium maculatum</i> , cyanide, ethylene glycol, insulin, malathion, methanol, tricyclic antidepressants
Liver ^{4,6,7,10,14}	Brodifacoum, carbon monoxide, <i>Conium maculatum</i> , cyanide, ethylene glycol, insulin, malathion, methanol, methaqualone, tricyclic antidepressants
Lung ^{5,7,14,25,27,29}	Brodifacoum, carbon monoxide, methanol
Pancreas ^{6,7,10,25}	Acetaminophen, brodifacoum, carbon monoxide, <i>Conium maculatum</i> , cyanide, ethylene glycol, methanol, tricyclic antidepressants
Skin ^{7,27}	Cyanide, methanol

^aCan be cadaveric procurement.

TABLE SC2–2. Xenobiotic Related Deaths Resulting in Successful Organ Donation

- β -Adrenergic antagonists
- Alkylphosphate
- Barbiturates
- Benzodiazepines
- Brodifacoum
- Carbamazepine

Carbon monoxide
Cardioactive steroids
Chlormethiazole
Conium maculatum
Cyanide
Ethanol
Ethylene glycol
Glibenclamide
Ibuprofen
Insulin
Malathion
Methaqualone
Meprobamate
Methanol
Propoxyphene
Tricyclic antidepressants

Probably more critical to transplantation success is adequate tissue perfusion and well-maintained cellular morphology. For example, patients suffering brain death from acetaminophen poisoning are not suitable liver donors given the hepatotoxicity. Alternatively, xenobiotics considered toxic to organ function by impairing enzymes have resulted in successful transplantation if the cellular structure is otherwise maintained. For example, a death from cardioactive steroid poisoning did not preclude successful heart transplantation even when the donor had a bradydysrhythmia, an elevated serum digoxin concentration, and required cardiopulmonary resuscitation.³⁴ Similarly, the liver of a patient poisoned with brodifacoum was transplanted after administration of fresh frozen plasma and vitamin K₁. The recipient's international normalized ratio (INR) post-transplant was 2 and corrected rapidly with supportive care. Recipient concentrations of brodifacoum were not reported and not clearly causative of the elevated INR.²⁹ In both examples, the target of toxicity was enzymatic and the tissue morphology was otherwise minimally affected. Organs from a patient who suffered hypoxic brain death after malathion poisoning were procured 2 weeks after the exposure at which time no further evidence of acute cholinergic toxicity was present and successfully transplanted.⁵ Most transplant failures from poisoned donors are due to rejection, sepsis, or technical reasons. The one year survival in recipients from poisoned donors approximates that from nonpoisoned donors; one series reported at 75% survival.¹² In another review, 5-year survival rates were between 33% and 100%, with heart transplant recipients the lowest.⁹

Ideally, a comprehensive international registry of transplants from poisoned donors will be established to improve understanding of transplants from such patients. It appears that patients who suffer brain death from poisoning are potentially suitable donors when cellular infrastructure is preserved.^{22,24,26,38} Consideration for organ procurement should not be limited by the xenobiotic.

SUMMARY

- Organ procurement from poisoned donors may reach success rates similar to non-poisoned donors when carefully selected.
- Clinically significant xenobiotic concentrations have not been reported in organ recipients.
- Adequate tissue perfusion is important for the viability of a transplanted organ, regardless of the primary toxicological insult.

PART C

**THE CLINICAL BASIS OF MEDICAL
TOXICOLOGY**

CASE STUDY 1

History A 22 year-old man was brought to the emergency department after being found unconscious at a movie theater. In the field the paramedics inserted an intravenous (IV) line, performed a rapid reagent glucose test that was recorded as 88 mg/dL, and placed the patient on oxygen via nasal cannula at 4 L/min when his room air pulse oximetry was determined to be 91%. The patient had no medical records at the receiving hospital, and no useful information was found among his belongings.

Physical Examination On arrival to the hospital he was deeply unconscious with no response to sternal rub. Vital signs were: BP, 92/56 mm Hg; P, 52 beats/min; RR, 10 breaths/min; T, 97.4°F (36.3°C); oxygen saturation, 98% on 4 L O₂/min; a repeat rapid reagent glucose was unchanged. Examination was notable for 2 to 3 mm pupils that responded to light, normal oculoccephalic testing, nearly flaccid muscle tone, and downgoing toes bilaterally. His head was without signs of trauma and his neck was supple. Examination of the chest revealed scattered coarse breath sounds and a regular heart rhythm with normal heart sounds and no murmurs. The abdomen was soft with quiet bowel sounds and no abnormalities were noted on the skin or extremities. When oxygen was removed, his saturation fell to 92%, and a continuous end-tidal CO₂ monitor measured 48 mm Hg.

Immediate Management Given the patient's hypoventilation and small pupils graded doses of naloxone were given (0.04, 0.1, and 2 mg IV) without response (Antidotes in Depth: A4). On further examination, the patient's gag reflex was absent prompting endotracheal intubation, which was performed without medications, and the patient was attached to a mechanical ventilator. A postintubation arterial blood gas, a complete blood count, electrolytes, and ethanol and acetaminophen (APAP) concentrations were obtained. Electrocardiography (ECG) showed sinus bradycardia with normal axis and intervals, and no ST segment or T-wave abnormalities were observed. A total of 1 L of 0.9% sodium chloride was infused and his blood pressure increased to 102/60 mm Hg, with no change in his pulse. A nasogastric tube was inserted through which 60 g of activated charcoal was instilled into the stomach.

What Is the Differential Diagnosis? This patient has deep coma, with relatively unremarkable vital signs (mild hypotension, bradycardia, and hypoventilation) and an unremarkable physical examination. The differential diagnosis is extensive and includes many xenobiotics from diverse chemical classes. The most common causes are listed in [Table CS1–1](#). In many cases it is not necessary to establish the correct diagnosis, but rather to exclude diagnoses that require specialized care or are amenable to specific interventions.

TABLE CS1–1. Common Causes of Coma with Relatively Normal Vital Signs and Unremarkable Physical Examination

Anticonvulsants	Ethanol
Antidepressants	Gabapentin and pregabalin
Antipsychotics	γ-Hydroxybutyric acid
Baclofen	Inhalants
Clonidine and other centrally acting α-adrenergic agonists	Insulin secretagogues
	Sedative-hypnotics

What Clinical and Laboratory Analyses Help Exclude Life-Threatening Causes of This Patient's Presentation?

Either a rapid reagent glucose determination should be obtained or hypertonic dextrose should be administered in every comatose patient ([Chap. 4](#) and Antidotes in Depth: A12). A normal blood glucose concentration or failure to respond to an appropriate dose of hypertonic dextrose essentially excludes hypoglycemia. When hypoventilation is present, a trial of naloxone is indicated, because recognizing that patients who have overdosed on clonidine and similarly acting antihypertensives may respond (Antidotes in Depth: A4). A screening ECG is essential and may guide diagnosis and management ([Chap. 16](#)). Prolongation of the QRS complex occurs with some antidepressants, antipsychotics, and anticonvulsants, and it may indicate the need to administer hypertonic sodium bicarbonate (Antidotes in Depth: A5). In addition, prolongation of the QT interval is commonly recognized with many antipsychotic and antidepressant overdoses. Although metabolic acidosis with an elevated anion gap is not typical of the xenobiotics listed, it might be indicative of a serious co-ingestant. Similarly, deep coma is not expected following a typical APAP overdose, but APAP is commonly ingested and co-formulated with sedatives and opioids.

When a patient presents with coma, relatively normal vital signs, and an unremarkable examination, and if ECG results and [glucose], oxygenation, [anion gap], and [acetaminophen] are normal or can be corrected, then the patient will likely do well with supportive care.

Further Diagnosis and Treatment The arterial blood gas and electrolytes showed no evidence of acidosis or anion

gap. Other than bradycardia, the ECG was normal. A serum [APAP] was 162 µg/mL. Because the time of ingestion was unknown IV, N-acetylcysteine (NAC) was initiated (Antidotes in Depth: A3). After some time a family member was contacted who disclosed that the patient had several previous suicide attempts and was known to be taking phenobarbital. A serum phenobarbital concentration was obtained on original blood in the laboratory and was reported to be 132 µg/mL. A bicarbonate infusion was started to alkalinize the urine of the patient (Antidotes in Depth: A5). A 21 hour NAC regimen was completed at which time the patient's [APAP] was not detectable and the aminotransferases were within normal limits. Over the next 48 hours the patient regained consciousness and was extubated. A consultation with a psychiatrist determined the need for involuntary hospitalization and the patient was transferred to the psychiatric service.

SECTION I

A. ANALGESICS AND ANTIINFLAMMATORY MEDICATIONS

35 ACETAMINOPHEN

Robert G. Hendrickson

HISTORY AND EPIDEMIOLOGY

By the late 1800s, both phenacetin and acetanilide were used as analgesics and antipyretics, but their acceptance was limited by significant side effects including methemoglobinemia. N-acetyl-p-aminophenol (APAP) is a major metabolite of phenacetin and acetanilide, and is responsible for, both analgesia and antipyresis. APAP was synthesized in 1878 and has a low risk of causing methemoglobinemia. N-acetyl-p-aminophenol is referred to as acetaminophen (N-**acetyl**-para**aminophenol**) in the United States, Canada, Japan, and several other countries and as paracetamol (para-acetylaminophenol) in most other areas of the globe. Both terms are abbreviations of the chemical name. APAP was first used clinically in the United States and the United Kingdom in the mid 1950s, but its widespread acceptance was delayed until the 1970s because of concerns of the toxicities of its precursors. APAP has since proved to be a remarkably safe xenobiotic at appropriate dosage, which has led to its popularity. APAP is available in a myriad of single-agent dose formulations and delivery systems, and in a variety of combinations with opioids, other analgesics, sedatives, decongestants, expectorants, and antihistamines.¹⁸⁴ The diversity and wide availability of APAP products dictate that APAP toxicity be considered not only after identified ingestions but also after exposure to unknown or multiple xenobiotics in settings of intentional overdose, abuse, and therapeutic misadventures.

Despite enormous experience with APAP toxicity, many controversies and challenges remain unresolved. New formulations and new analogs are being introduced, that will require reassessments of the available knowledge.^{57,113,326} To best understand the continuing evolution in the approach to APAP toxicity, it is critical to start with certain fundamental principles and then to apply these principles to both typical and atypical presentations in which APAP toxicity must be considered.

PHARMACOLOGY

APAP is an analgesic and antipyretic with weak peripheral antiinflammatory and antiplatelet properties. Analgesic activity is reported at a serum [APAP] of 10 µg/mL and antipyretic activity at 4 to 18 µg/mL.³⁴⁵

APAP has a unique mechanism of action among the analgesic antipyretics. Most of the nonsteroidal antiinflammatory drugs (NSAIDs) occupy the cyclooxygenase (COX) binding site on the enzyme prostaglandin H₂ synthase (PGH₂) and prevent arachidonic acid from physically entering the site and being converted to prostaglandin H₂. APAP also inhibits prostaglandin H₂ production but does so indirectly by reducing a heme on the peroxidase (POX) portion of the PGH₂,¹⁹⁹ and indirectly inhibiting COX activation.^{13,154,195} In this way, APAP function is highly dependent on cellular location and intracellular conditions.^{12,111,231} APAP strongly inhibits prostaglandin synthesis where concentrations of POX and arachidonic acid (“peroxide tone”) are low such as in the brain.^{90,101} In conditions of high peroxide tone, such as inflammatory cells (macrophages) and platelets, prostaglandin synthesis is less affected by APAP,^{13,39,111,125,195,221,231} although this is not universal.¹⁵ This dissociation explains the strong central antipyretic and analgesic effect of APAP but weak peripheral antiinflammatory and antiplatelet effects. Functionally, APAP predominantly acts as a central indirect inhibitor of COX-2 enzymes,^{136,219,221} with some mild peripheral COX-2 inhibition¹⁸⁶ and minimal COX-1 inhibition (Chap. 37).⁵⁴

Antipyresis and analgesia are predominantly mediated by this central indirect COX-2 inhibition and the resulting decrease in prostaglandin E₂ (PGE₂) synthesis.^{98,111,169,189,221} Additional analgesic effects may be mediated by indirect stimulation by APAP of serotonergic and opioid descending pathways or activation of the cannabinoid system. Stimulation of descending serotonergic pathways is demonstrated in rats³⁶ and humans,^{111,236} and the analgesic effect of APAP may be inhibited by several serotonin antagonists or serotonin depletion.^{6,236,237,238,268} In rats, the analgesic effect of APAP is attenuated by opioid receptor antagonists.^{49,269} However, APAP binds poorly to opioid receptors,^{248,249,250} and the exact mechanism of opioid stimulation remains unexplained.²⁷⁰ Finally, activation of the central or peripheral endogenous cannabinoid system, potentially from an APAP metabolite,¹³⁸ has been theorized but remains controversial.^{27,73,124,230}

PHARMACOKINETICS

After ingestion of a therapeutic dose, immediate-release APAP is rapidly absorbed from the small intestine with a time to peak [APAP] of approximately 30 minutes for liquid formulations and 45 minutes for tablet formulations.^{7,83,104} Extended-release APAP has a time to peak of 1 to 2 hours but is almost entirely absorbed by 4 hours.⁸⁵ The time to peak may be delayed by food⁸³ and co-ingestion of opioids or anticholinergics.¹²³ The oral bioavailability is 60% to 98%,²⁵² and the volume of distribution (Vd) is 1 L/kg.^{7,9,104} Peak [APAP] after recommended doses typically ranges from 8 to 20 µg/mL.^{7,104} After administration of 20 to 25 mg/kg rectal suppositories, the peak [APAP] ranges from 4.1 to 13.6 µg/mL, the time to peak [APAP] is 2 to 4 hours (range, 0.4–8 hours), and the bioavailability is 30% to 40%.^{18,33,122} APAP is available in the intravenous form as an APAP solution in the United States, United Kingdom, Australia, New Zealand, and many other countries as well as a prodrug (eg, propacetamol) in the United Kingdom. The time to peak of the intravenous formulations are immediate (< 15 minutes), and peak [APAP] after a 1 g infusion is approximately 30 µg/mL, and after a 2 g infusion is approximately 75 µg/mL with a large range of 31 to 161 µg/mL.^{102,116,235} The Vd is higher in both pregnant women and neonates, while clearance rates are higher in pregnant women and lower in neonates.^{5,174} APAP has total protein binding of 10% to 30% that does not change in overdose.²⁰⁸ APAP crosses the placenta, the blood–brain barrier, and in small amounts (< 2% of ingested dose), into breast milk.^{108,188,225}

After absorption, approximately 90% of APAP normally undergoes hepatic conjugation with glucuronide (40%–67%), mostly via UGT1A6, and sulfate (20%–46%), mostly via SULT1A1, to form inactive metabolites, which are eliminated in the urine. A small fraction of unchanged APAP (< 5%) and other minor metabolites reach the urine.²¹³ The remaining fraction, approximately 5% in therapeutic doses, is oxidized by CYP2E1 (and, to a lesser extent, CYP3A4, CYP2A6, and CYP1A2),^{130,198} resulting in the formation of N-acetyl-p-benzoquinoneimine (NAPQI).⁶⁵ Glutathione (GSH) quickly combines with NAPQI,²¹² and the resulting complex is converted to nontoxic cysteine or mercaptate conjugates, which are eliminated in the urine (Fig. 35–1).^{207,213} The elimination half-life of APAP is approximately 2 to 3 hours after a nontoxic dose^{4,246} but may become prolonged in patients who develop hepatotoxicity.

FIGURE 35–1. Important routes of APAP metabolism in humans and mechanisms of N-acetylcysteine (NAC) hepatoprotection. NAC¹ augments sulfation, NAC² is a glutathione (GSH) precursor, NAC³ is a GSH substitute, and NAC⁴ improves multiorgan function during hepatic failure and possibly limits the extent of hepatocyte injury. APAP = N-acetyl-p-aminophenol = acetaminophen.

TOXICOKINETICS

After most oral overdoses, the majority of APAP absorption occurs within 2 hours and peak plasma concentrations generally occur within 4 hours. Later peaks or double peaks are rarely documented in overdoses and have generally occurred after large ingestions (> 50 g) with or without co-ingested antimuscarinics.^{31,134,303,332} Evidence suggests that NAPQI production is largely the result of activity of the CYP2E1 enzyme after both therapeutic and supratherapeutic doses of APAP.^{91,130} Contributions of CYP1A2, CYP3A4, and CYP2A6 to the production of NAPQI in humans are small and insignificant in most cases, but they may be variable, depending on individual host factors and dosage.^{130,233,251,320} After clinically significant overdose, nontoxic sulfation metabolism of APAP may become saturated.¹⁶⁶ The amount of NAPQI formed is increased out of proportion to the APAP dose and may account for up to 20% to 50% of metabolism in patients with hepatotoxicity.²⁴⁴ Glucuronidation rates are likely not saturatable in humans (Fig. 35–1).^{80,166,242}

The toxicokinetics of intravenous APAP are largely unknown. Doses of 75 mg/kg and 146 mg/kg have produced 4 hour [APAP] of 35 µg/mL and 117 µg/mL, respectively, with half-lives ranging from 2 to 6 hours. One patient who received a 75 mg/kg intravenous APAP dose had a 1 hour [APAP] of 72 µg/mL.

PATHOPHYSIOLOGY

The safety of appropriate APAP dosing results from the availability of electron donors such as reduced GSH and other thiol (S-H)-containing compounds. After therapeutic APAP dosing, GSH supply and turnover far exceed that required to detoxify NAPQI. With ample GSH supply, NAPQI is largely bound by GSH, and no toxicity occurs, although NAPQI-cysteine protein adducts do form within the liver and some are released into the serum.^{133,206} After overdose, the rate and quantity of NAPQI formation outstrip supply and turnover of GSH, resulting in the release of NAPQI within the cell. NAPQI then rapidly binds to hepatocyte constituents, including the cysteine portion of proteins, producing protein adducts within the liver. In animal experiments, hepatotoxicity becomes evident only when hepatic [GSH] decreases to 30% of baseline or below.²¹¹

When NAPQI formation overwhelms the supply of thiol-containing compounds, it covalently binds^{92,240} and arylates proteins throughout the cell,^{63,149,153} inducing a series of events that result in cell death.¹⁵¹ Covalent binding and arylation occur rapidly after GSH depletion.^{32,149,151,254} Both covalent binding and GSH deficiency are necessary for hepatotoxicity; however, the selective arylation of specific cellular proteins is more predictive of toxicity than total covalent binding.^{63,143}

Protein binding of NAPQI and the formation of protein adducts does not imply toxicity as adducts are formed at therapeutic [APAP]. However, highly elevated concentrations of protein adducts in the serum may be indicative of cellular necrosis and hepatotoxicity. After covalent protein binding and GSH depletion occur, a cascade of events follows that alters normal cell function and impairs cell defenses against endogenous reactive oxygen species.^{153,254,323} This cascade can be ameliorated with N-acetylcysteine (NAC) even after covalent binding occurs.^{45,81,106,149,254} These events include mitochondrial dysfunction,^{50,84} an increase in mitochondrial permeability,²⁵⁴ mitochondrial oxidant stress or peroxynitrite formation,^{66,135,164} hepatocellular hypoxia,²⁶⁴ DNA fragmentation,⁶⁶ which results from interactions with topoisomerase 2- α ,^{20,287} calcium dyshomeostasis,^{216,323,324} lipid peroxidation,^{118,337} nitric oxide release,²⁶⁵ inflammatory cell mobilization and activation,^{140,177,191} inflammatory cytokine release,^{148,149,177,191} and up- or downregulation of protein expression.^{30,143,144,264} Which specific events are critical and irreversibly commit the cell to death is not known.

The final pathway of hepatic cell death is predominantly cellular necrosis.¹²¹ Cellular injury leads to release of intracellular molecules, which further activate the immune system. Some of these intracellular components that are released from necrotic cells may be used as biomarkers of hepatic injury and include aspartate aminotransferase (AST), alanine aminotransferase (ALT), microRNA 122 (miRNA-122), high-mobility group box-1 protein (HMGB-1), keratin-18 protein (K-18), and protein adducts.^{10,11,310} Apoptosis may occur after activation of the immune system in response to this cellular necrosis,^{1,11} although there is evidence that apoptosis may occur early in APAP toxicity as well.^{197,253} Macrophages, neutrophils, and inflammatory cells infiltrate after necrosis^{140, 142,185,191} followed by a cascade of inflammatory cytokines such as interleukin (IL) 1, IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1).^{140,148,149,191} Hepatocellular destruction caused by secondary inflammation, impairment of microcirculation,²¹⁰ and hepatic nitric oxide release^{149,264} are all demonstrated, although none appear to be necessary for hepatic injury.^{66,144,145,181}

Hepatotoxicity initially and most profoundly occurs in hepatic zone III (centrilobular) because this zone is the area with the largest concentration of oxidative metabolism (CYP2E1; Fig. 23–1). In more severe hepatotoxicity, necrosis may extend into zones II and I, destroying the entire hepatic parenchyma.

Kidney injury after acute overdose is typically acute tubular necrosis (ATN) that may be caused by local production of NAPQI by renal CYP2E1 enzymes.^{42,90,139} However, several other nephrotoxic mechanisms have been proposed.¹²⁸ Conversion of APAP and hepatically derived APAP–GSH²¹⁵ to nephrotoxic p-aminophenol⁵³ are both demonstrated in selected animal models.^{103,202} NAPQI formation via renal prostaglandin H synthase³²⁹ and prostaglandin-mediated renal medullary ischemia²⁴⁵ are also suspected of contributing to chronic analgesic nephropathy from APAP alone or in combination with other analgesics.^{103,267} In patients with hepatic failure, volume depletion and hepatorenal syndrome may be the most important contributory cofactors because the rate of acute kidney injury is similar regardless of the cause of hepatic failure.³⁴⁴ Dose-related renal potassium wasting^{107,232,337} after acute APAP overdose may be related to APAP-induced renal vasoconstriction due to COX inhibition or a NAC effect, or both.²³²

Direct injury to organs other than the liver and kidney is rarely reported. The mechanism of early central nervous system (CNS) depression after APAP ingestion is undefined, but theoretical mechanisms include serotonin and opioid effects as well as APAP-induced CNS GSH depletion.⁵⁶ Metabolic acidosis and elevated lactate early after massive APAP ingestion may be the result of alterations in mitochondrial respiratory function, but the exact mechanism is unknown.^{48,95,101,168,313} Rare cases of metabolic acidosis with 5-oxoprolinemia and 5-oxoprolinuria are reported and appear to be more likely in women with chronic APAP use and chronic kidney disease.^{44,99,137,180} In this rare condition, it is theorized that chronic APAP use combined with acute oxidative stress and inflammatory mediators may lead to an alteration of the γ -glutamyl cycle and elevations of γ -glutamylcysteine and 5-oxoproline.^{44,87,137}

The remaining sequelae of severe toxicity are secondary effects of fulminant hepatic failure rather than direct APAP effects, and the pathophysiology of these complex multisystem problems is well described.¹⁸⁵ For example, myocardial

injury and pancreatitis are both reported in patients with APAP-induced fulminant hepatic failure. The ability of NAC to ameliorate secondary multiorgan failure via extrahepatic mechanisms suggests that the oxidation of vital thiols and the loss of normal microvascular function are important components of secondary organ failure.^{127,157}

CLINICAL MANIFESTATIONS

Early recognition and treatment of patients with APAP poisoning are essential to minimize morbidity and mortality. This task is made difficult by the lack of early predictive clinical findings. The first symptoms after APAP overdose may be those of hepatic injury, which develop many hours after the ingestion, when antidotal therapy will have diminished efficacy.

The clinical course of acute APAP toxicity can be divided into four stages.²⁶² During stage I, hepatic injury has not yet occurred, and even patients who ultimately develop severe hepatotoxicity may be asymptomatic. Clinical findings, when present, are nonspecific and may include nausea, vomiting, malaise, pallor, and diaphoresis. Laboratory indices of hepatic function are normal. In rare cases of massive overdose, a decreased level of consciousness,^{88,114,168,258,311} metabolic acidosis and elevated lactate,^{114,168,205,258,284,341,354} due to inhibition of electron transport by APAP, NAPQI, or both,^{94,95,114} and even death^{37,291} may occur during this stage in the absence of signs or symptoms of hepatotoxicity.^{37,100,168,258,284,311,355} These clinical findings should never be attributed to APAP alone without thorough evaluation of other possible causes.

Stage II represents the onset of hepatic injury, which occurs in fewer than 5% of those who overdose.²⁹⁹ AST is the most sensitive, widely available measure to detect the onset of hepatotoxicity, and AST abnormalities always precede evidence of actual hepatic dysfunction (prolonged prothrombin time {PT}, international normalized ratio {INR}, elevated bilirubin concentration, hypoglycemia, encephalopathy, and metabolic acidosis). When stage II occurs, onset of AST elevation is most common within 24 hours after ingestion but is nearly universal by 36 hours.^{117,289} In the most severely poisoned patients, AST concentrations may increase as early as 12 hours after ingestion.^{117,289} Symptoms and signs during stage II vary with the severity of hepatic injury. By convention, acetaminophen-induced hepatotoxicity is defined as a peak ALT concentration above 1000 IU/L. Although lower peak concentrations of AST or ALT represent some injury to hepatic tissue, they rarely have any clinical relevance.

Stage III, defined as the time of maximal hepatotoxicity, most commonly occurs between 72 and 96 hours after ingestion. The clinical manifestations of stage III include fulminant hepatic failure with encephalopathy and coma, and, rarely, hemorrhage. Results of laboratory studies are variable; AST and ALT concentrations above 10,000 IU/L are common, even in patients without other evidence of hepatic failure. Much more important than the degree of aminotransferase concentration elevation, abnormalities of PT and INR, glucose, lactate, creatinine, and pH are essential determinants of prognosis and treatment.

Renal function abnormalities are rare (< 1%) overall,^{243,334} but they can occur in as many as 25% of patients with significant hepatotoxicity²⁴³ and in 50% to 80% of those with hepatic failure.^{176,228,344} Renal abnormalities may be more common after sustained, repeated excessive dosing¹⁷⁶ and in adolescents and young adults.^{40,201,217} After acute ingestions, elevations of serum creatinine typically occur between 2 and 5 days after ingestion, peak on days 5 to 7 (range, 3–16 days),³³⁴ and normalize over 1 month.²⁰¹ When severe acute kidney injury necessitating hemodialysis occurs, it nearly always occurs in patients with marked hepatic injury. Patients with hepatorenal syndrome are commonly treated with continuous renal replacement therapy, and among those who survive, kidney failure generally resolves within one month.^{190,228} Infrequently, mild acute kidney injury occurs without elevations in aminotransferase concentrations.^{3,40,62,89}

Fatalities from fulminant hepatic failure generally occur between 3 and 5 days after an acute overdose. Death results from either single or combined complications of multiorgan failure, including acute respiratory distress syndrome, sepsis, cerebral edema, or, rarely, hemorrhage. Patients who survive this period reach stage IV, defined as the recovery phase. Survivors have complete hepatic regeneration, and no cases of chronic hepatic dysfunction have ever been reported. The rate of recovery varies; in most cases, AST, pH, PT, and INR, and lactate are normal by 7 days in survivors of acute overdoses. ALT may remain elevated longer than AST, and creatinine may be elevated for more than one month. The recovery time is much longer in severely poisoned patients, and histologic abnormalities may persist for months.^{187,200,239}

DIAGNOSTIC TESTING

Assessing the Risk of Toxicity

Principles Guiding the Diagnostic Approach. Most APAP exposures result in no toxicity, and the overall mortality rate after acute APAP ingestion is less than 0.5%.²⁹⁹ However, APAP is now the leading cause of acute hepatic failure in the United States and much of the developed world.¹⁷⁶ To maintain the seemingly divergent goals of avoiding the enormous cost of over-treatment while minimizing patient risk, clinicians must understand the basis for and sensitivity of current toxicity screening methods. A discussion of the diagnostic approach follows.

When considering risk determination, it is useful to separate different categories of APAP exposure. There is an extensive body of experience and literature on acute overdose in typical circumstances, permitting a more systematic approach with demonstrated efficacy. For issues related to repeated supratherapeutic APAP dosing, uncertain circumstances, new APAP formulations, and many other permutations, there is an important conceptual framework for decision-making but little in the way of validated strategies. For these challenges, the central concepts and one approach are presented here, with the understanding that the challenges continue to evolve and that more than one approach may have validity.

The ideal model for determining risk after APAP overdose would assess the individual's metabolic enzyme activity (CYP2E1, UDP-glucuronosyl transferase, and sulfotransferase activity), the amount and rate of NAPQI formation, the availability of hepatic GSH, and the balance of NAPQI formation and hepatic GSH turnover. At present, none of these measures is available to clinicians.

Plasma GSH concentration can be measured or approximated using the plasma γ -glutamyl transferase (GGT) concentration but have an uncertain relationship to hepatic GSH availability.^{283,302}

Protein adducts indicate intracellular binding of NAPQI to hepatocyte proteins^{78,147,247,339} and can be determined experimentally, but have been inadequately studied to be useful in risk assessment or the assignment of causality of hepatic failure. After over-exposure to APAP, NAPQI is not immediately bound to GSH and is released within the cell to bind with the cysteine components on proteins. One of these protein-APAP adducts is 3-(cysteinyl-S-yl)-APAP, for which there is a research assay. However, hepatic toxicity from APAP requires not only protein binding, and therefore protein adducts, but an inflammatory cascade to produce cell necrosis.³⁸ Therefore, protein adducts are signs of NAPQI binding, but not necessarily of toxicity. Animals exposed to APAP overdose develop elevated concentrations of serum protein adducts. However, those who are rescued with NAC have protein adducts within the liver, but little is spilled into the blood because hepatic cellular necrosis does not occur.^{34,133,149}

In humans with therapeutic dosing of APAP, protein adducts are usually detected in small quantities in the blood (< 0.5 nmol/mL), likely from intrahepatic protein binding followed by hepatic cellular turnover. However, concentrations of up to 1.0 nmol/mL have also been detected in patients with therapeutic dosing.¹³³ In humans after overdose, protein adducts are released into the serum and largely parallel the aminotransferases in their time-course. Peak concentrations are detected in 2 to 3 days and decrease with an elimination half-life of 1.7 days. Protein adducts remain detectable for up to 2 weeks.¹⁴⁶ A protein adduct concentration above 1.0 nmol/mL has been suggested as being consistent with an acute APAP overdose, but this recommendation will require further validation.¹³³

Other hepatic cellular components may be detected in serum during APAP toxicity and are being analyzed as biomarkers of hepatotoxicity. miRNA are small, noncoding RNA that regulate cell proteins by repressing mRNA.³¹⁰ miRNA-122 is the most abundant hepatic microRNA and is specific to the liver.³¹⁰ In human studies, miRNA-122 increases prior to other markers, such as ALT, and may be actively released from hepatocytes prior to cell lysis.³⁰⁹ [miRNA-122] correlates with peak ALT¹⁰ and peak INR.¹⁰ In patients with acute APAP overdose whose initial ALT is normal and in patients who are treated within 8 hours, [miRNA-122] is higher in those who develop hepatic injury,¹⁰ suggesting that it may be useful in differentiating low risk patients from high risk patients earlier than other markers.

Another biomarker, HMGB-1, is passively released by hepatocytes during necrosis. HMGB-1 is elevated in patients with APAP hepatotoxicity but not in those without hepatotoxicity and correlates with both peak ALT and INR. An acetylated form of HMGB-1 is secreted as an inflammatory mediator by macrophages and monocytes and increases only in patients with APAP toxicity who later either meet transplant criteria (King's College Criteria), die, or receive a hepatic transplant. This biomarker requires further study, but has promise as an earlier marker for more intensive treatment or for transplant.¹¹

Risk Determination Following Acute Overdose. Determining risk in a patient with acute overdose consists of determining the initial risk based on dosing history and then potentially further risk stratifying with serum [APAP].

Acute overdose usually is considered a single ingestion, although many patients actually overdose incrementally over a brief period of time. For purposes of this discussion, an acute overdose is arbitrarily defined as one in which the entire ingestion occurs within a single 8-hour period.⁷⁵ Doses of 7.5 g in an adult or 150 mg/kg in a child are widely disseminated as the lowest acute dose capable of causing toxicity.²⁴⁴ These standards are likely quite conservative but have stood the test of time as sensitive markers and have been corroborated with some data in humans.^{335,357} However, it is more likely that doses of at least 12 g in an adult or 200 mg/kg in a child are necessary to cause hepatotoxicity in most patients.^{214,335}

The adult standard may be considered less controversial than that for children because massive ingestions, unreliable histories, and factors that might predispose to toxicity occur primarily in adults, justifying continued use of 7.5 g as a screening amount to avoid missing serious toxicity. In patients younger than 6 years of age, with unintentional ingestions, use of a higher 200-mg/kg cutoff has been suggested^{52,214,315} and is likely appropriate but has been incompletely studied.

The dose history should be used in the assessment of risk only if there is reliable corroboration or direct evidence of validity. Although the amount ingested by history roughly correlates with risk of toxicity and an [APAP] over the treatment

line,^{21,335,357} historic information is not sufficiently reliable in all patients to exclude significant ingestion, particularly in patients with the intent of self-harm or drug abuse.³⁵⁷ In fact, suicidal patients with ingestions who do not confirm an ingestion of APAP may have a measurable concentration in 1.4% to 8.4% of cases^{14,194} and a concentration over the treatment line in up to 0.2% to 2.2%.^{14,194} Therefore, when the history suggests possible risk, the patient should be further assessed an [APAP].

Interpretation of [APAP] after acute exposures is based on adaptation of the Rumack-Matthew nomogram (Fig. 35–2).²⁵⁹ The original nomogram was based on the observation that untreated patients who subsequently developed AST or ALT concentrations above 1000 IU/L could be separated from those who did not on the basis of their initial [APAP]. A nomogram was constructed that plotted the initial concentration versus time since ingestion, and a discriminatory line was drawn to separate patients who developed hepatotoxicity from those who did not. The initial discriminatory line stretched from [APAP] of 300 µg/mL at 4 hours to 50 µg/mL at 12 hours but was lowered to between 200 µg/mL at 4 hours and 50 µg/mL at 12 hours after evaluation of additional patients.²⁵⁹ The half-life of APAP was not a factor in the development of the nomogram, and the slope of the treatment line is based on empirical clinical data and does not reflect any discriminatory APAP half-life or APAP kinetics.²⁵⁹ The nomogram is designed and validated using a single value obtained at or greater than 4 hours after ingestion to allow for complete APAP absorption. Although patients who develop hepatotoxicity may have APAP half-lives greater than 4 hours,^{246,292} plotting multiple points on the nomogram or using an APAP half-life to determine risk has not been adequately studied and has significant limitations.^{165,301} The nomogram was later extrapolated to 24 hours using the same slope of the original nomogram line.²⁵⁹

FIGURE 35–2. Rumack-Matthew nomogram (reconstructed) for determining the risk of APAP induced hepatotoxicity after a single acute ingestion. Serum concentrations above the treatment line on the nomogram indicate the need for N-acetylcysteine therapy.

It is important to realize that the line was based on aminotransferase concentration elevation rather than on hepatic failure or death, and it was chosen to be very sensitive, with little regard to specificity. Without antidotal therapy, only 60% of those with an initial [APAP] above this original line will develop hepatotoxicity as defined by aminotransferase concentrations above 1000 IU/L, but the risk of hepatotoxicity is not the same for all such patients. Elevated aminotransferase concentration develops in virtually all untreated patients with [APAP] far above the line, and serious hepatic dysfunction occurs frequently; the incidence of hepatotoxicity among untreated people with [APAP] immediately above the line is very low, and the risk of hepatic failure or death is far less.^{243,293}

The line used in the United States runs parallel to the original but was arbitrarily lowered by 25% to add even greater

sensitivity.^{259,262} The lower line, subsequently referred to as the treatment line or 150-line, starts at a concentration of 150 µg/mL at 4 hours following ingestion; declines with a 4 hour half-life, and ends at 4.7 µg/mL 24 hours following the overdose. The treatment line is one of the most sensitive screening tools used in medicine. The incidence of nomogram failures in the United States using this line is only 1% to 3% (depending on time to treatment).²⁵⁹ These infrequent “failures” may result from inaccurate ingestion histories, or may include patients with currently undefined risk factors for toxicity, including unique GSH handling or CYP enzyme activities.^{204,259}

In September 2012, the United Kingdom adopted a single nomogram line starting at 100 µg/mL at 4 hours (“100-line”) for all acute APAP ingestions.¹⁰⁹ This single 100-line replaced a two-tiered treatment protocol that treated low risk patients if either [APAP] exceeded the “200-line” and high risk patients if their [APAP] exceeded the “100-line”.³³³ The change was motivated by concern with regard to a small number of patients with [APAP] between the 100- and 200-lines who developed hepatic toxicity^{19,43,79,259,297,333} and a desire to simplify the treatment protocol. Why a 100-line was chosen by the UK Medicines and Healthcare Regulatory Agency and not a 150-line is not clear and has been questioned by several authors.^{109,204}

Based on these observations and more than 25 years of use, the 150-line should be considered adequate in nearly all cases and is reliable when rigorously followed. When using the APAP nomogram, it is essential to precisely define the time window during which APAP exposure occurred and, if the time is unknown, to use the earliest possible time as the time of ingestion. Using this approach, patients with [APAP] below the treatment line, even if only slightly so, do not require further evaluation or treatment for acute APAP overdose. This also applies to most patients with factors that may predispose them to APAP-induced hepatotoxicity. There appears to be adequate experience with acute APAP overdose in the settings of potentially predisposing factors such as chronic heavy ethanol use, chronic medication with CYP-inducing xenobiotics, and inadequate nutrition to recommend that no special approach is required in such cases. Further study is needed to determine if rare events, such as acute APAP ingestion in the setting of chronic isoniazid (INH) use,^{93,220,353} may uniquely predispose patients to toxicity and require alteration of this approach.

The goal should be to determine [APAP] at the earliest point at which it will be meaningful in decision-making. Therefore, measurement of [APAP] 4 hours after ingestion or as soon as possible thereafter is used to confirm the patient’s risk of toxicity and, thus, the need to initiate NAC. No established guidelines are available for the use of determinations made less than 4 hours after ingestion, and because of variability in absorption, such values have less predictive value. Although it is optimal to start NAC therapy as soon as possible after confirmation of risk, NAC is nearly 100% effective if started prior to 6 to 8 hours after ingestion.^{293,299} This allows clinicians some leeway to wait for the laboratory results before starting therapy in patients in whom the history of ingestion suggests that the 4h [APAP] will fall below the treatment line. However, it should be noted that delaying NAC therapy longer than 6 to 8 hours after ingestion may increase the patient’s risk. If there is any concern about the availability of an [APAP] before this time, then treatment with NAC should be initiated. In such cases, [APAP] still should be determined as soon as possible. The results, when they become available, should be interpreted according to the treatment line on the APAP nomogram and NAC either continued or discontinued on the basis of this result. In the unusual circumstance in which no determination of [APAP] can ever be obtained, evidence of possible risk by history alone is sufficient to initiate and complete a course of NAC therapy post ingestion.

Early Measurement of [APAP]. Measurement of [APAP] between 1 and 4 hours after ingestion may be helpful only to exclude ingestion of APAP. If [APAP] is undetectable in this time frame, significant APAP overdose can likely be excluded. However, an [APAP] that is detectable between 1 and 4 hours cannot be definitively interpreted and, unless undetectable, mandates repeat testing at 4 hours.

Determination of Risk When the Acetaminophen Nomogram Is Not Applicable

Risk Determination When Time of Ingestion Is Unknown. With careful questioning of the patient, family, and others, it is almost always possible to establish a time window during which the APAP ingestion must have occurred. The earliest possible time of ingestion (“worst-case scenario”) is used for risk-determination purposes. If this time window cannot be established or is so broad that it encompasses a span of more than 24 hours, then the following approach is suggested. Determine both [APAP] and AST concentrations. If the AST concentration is elevated, regardless of [APAP], treat the patient with NAC. If the time of ingestion is completely unknown and [APAP] is detectable, it is prudent to assume that the patient is at risk and to initiate treatment with NAC. If [APAP] is undetectable and the AST concentration is normal, there is little evidence that subsequent consequential hepatic injury is possible²⁹¹ and NAC is unnecessary.

Risk Assessment Following Extended-Release Acetaminophen. Extended-release formulations of APAP exist in the United States, Australia, New Zealand, and other countries worldwide. The pills available in the United States consists of a 325 mg immediate-release APAP dose and an additional 325 mg dose designed for delayed dissolution.⁷⁶ The pills found in Australia and New Zealand (all three have identical contents) consist of a 665 mg bilayer tablet with 206 mg in the immediate release form and 459 mg in a sustained-release gel matrix.^{112,113} Both products result in the immediate release of APAP with delayed release of an additional dose. Pharmacokinetic analysis of the US product reveals that the majority of

APAP is absorbed within 4 hours,^{85,327} the peak [APAP] is within 4 hours,^{58,85,312} and a small number of patients may have an initial [APAP] below the treatment line, but then have a subsequent [APAP] above the treatment line (“nomogram crossing”).^{58,327} “Nomogram crossing” has been described with the Australian and New Zealand products as well.¹¹² This “nomogram crossing” is not unique to the extended-release products and occurs in up to 10% of acute ingestions of immediate-release APAP.⁴⁶ There is little evidence that nomogram crossing affects outcome⁷⁶ and no evidence that an alternate approach to extended-release products should be used. In a 9 year review of 2596 extended-release APAP overdoses in the United States, one death was reported from acute overdose and there was no increased risk over immediate-release APAP.⁷⁶ In Australia and New Zealand, five cases of overdose have been described. Three patients had an [APAP] over the treatment line at 4 hours or later, were treated with NAC and did not develop hepatotoxicity.¹¹² One patient ingested 79 g of extended-release APAP, developed a double-hump [APAP] and a peak [APAP] of about 470 µg/mL at 10 to 15 hours, was treated with early NAC and developed mild aminotransferase elevations.¹¹³ The final patient had an [APAP] that was just below the treatment line at 4 hours, just above the line at 6 hours, was treated with NAC, and also did not develop hepatotoxicity.^{112,113} Certainly, a single [APAP] can reliably be plotted on the treatment nomogram after ingestion of the US APAP extended-release ingestion. Whether an alternative approach will be necessary for the Australian and New Zealand products, or any other new formulation, will require additional study.

Acute Overdose of Intravenous Acetaminophen. Several intravenous APAP and prodrug APAP products exist worldwide and the US Food and Drug Administration (FDA) approved an intravenous APAP product in 2010 (intravenous APAP, 1 g in 100 mL).¹¹⁵ Experience with intravenous APAP overdoses is limited, but 23 intravenous APAP overdoses have been described, as well as one case of hepatic toxicity with coagulopathy.^{22,115,224} Errors commonly occur in young children and include 10-fold dosing errors, confusion between mg and mL, and incorrect route (oral product given intravenously).^{23,115}

The approach described here is likely conservative and unstudied and is based on limited information including a well-documented case in which a dose of 90 mg/kg intravenously produced a 6h [APAP] of 38 µg/mL with hepatic toxicity and coagulopathy.²² This approach is reasonable based on current data, but should be modified as more information emerges. If a single dose error occurs that is in excess of 60 mg/kg, then immediate treatment with NAC is recommended.^{22,115} If a single dose is given but the exact dose is unknown, then an [APAP] should be drawn and plotted on the nomogram using a new, lower line starting at 50 µg/mL at 4 hours and decreasing with a 4 hour half-life. If the concentration is above this “50-line,” then treatment with NAC is indicated.²² There are few data on which to base a treatment decision prior to 4 hours if the dose is unknown. However, in this circumstance, there is likely no harm in waiting for a 4 hour [APAP] prior to initiating therapy. Finally, patients receiving multiple supratherapeutic doses of intravenous APAP should be treated with NAC if there is evidence of hepatic toxicity (eg, elevated aminotransferase concentrations or evidence of hepatic failure) or if there is evidence of APAP accumulation (eg, [APAP] is above therapeutic concentrations that are expected for the last dose).¹¹⁵

Risk Determination Following Repeated Supratherapeutic Ingestions (or Chronic Overdose). No well-established guidelines are available for determining risk after chronic exposure to APAP. Conceptually, several factors must be considered before assessing and determining an individual’s risk of toxicity. It has been well established that therapeutic dosing of APAP is safe; however, some risk factors may put individual patients at risk for toxicity at supratherapeutic doses.

The chronic ingestion of “maximal therapeutic” doses (4 g/day) in normal adults without special circumstances appears to be safe. Several randomized, controlled trials have used maximal therapeutic doses of APAP (4 g/day) in thousands of patients over periods from 4 weeks to 2 years with no reported increase in adverse events or hepatic injury. A transient increase in aminotransferases of one to three times normal, but rarely up to 10 times normal is detected in some patients taking therapeutic doses,^{2,338} but these abnormalities resolve spontaneously despite continued use and have not led to hepatic dysfunction.^{172,338} Finally, several studies have evaluated abstaining chronic alcoholics administered APAP 4 g/day for up to 10 days with no evidence of hepatic damage, although elevations in aminotransferases were detected in both APAP and control groups.^{72,173}

In 2009, an FDA advisory committee recommended to the FDA to decrease the daily dose of APAP to 3250 mg/day and in 2011 McNeil Pharmaceuticals limited its recommended daily dose for the 500 mg tablet to 3000 mg/day. This recommendation and the change in dosing was neither evidence based nor based on any safety data. The recommended daily dose for the 325 mg tablet and 650 mg extended-relief tablet remains at 3900 mg/day. The FDA did not mandate this reduction of daily dosing.¹⁷⁰

Although therapeutic dosing appears to be safe, repeated supratherapeutic ingestions (RSTIs) may lead to toxicity. Given the amount of APAP use, the incidence of serious APAP toxicity after repeated doses is small, and hepatotoxicity appears to occur only after massive dosing¹⁸⁸ or prolonged excessive dosing. The risk of hepatotoxicity is likely proportional to both the total amount of APAP ingested and the duration of the exposure; however, exact cutoffs for safe dosing are difficult to determine and are likely subject to factors related to the individual.

Although short-term prospective studies of supratherapeutic dosing (6–8 g/day) have not identified alterations in APAP kinetics or hepatotoxicity,¹⁰⁵ several series and case reports have identified patients with hepatotoxicity who retrospectively report therapeutic or slightly supratherapeutic doses. Retrospective dosage reporting is prone to significant errors and issues in which those giving the history may be unable or unwilling to report or estimate ingestions accurately. Cases describing hepatic toxicity after in-hospital therapeutic doses exist, but are exceedingly rare, involve unusual risk factors, and demonstrate multifactorial hepatic injury.^{55,61} Furthermore, because APAP is commonly used in patients with chronic heavy ethanol use and viral infections, it is unclear in which cases APAP was causative, contributory, or unrelated to hepatotoxicity.

Conceptually, the groups that are at “high risk” for hepatotoxicity after RSTI of APAP have either potentially increased activity of CYP2E1 and therefore proportionally increased NAPQI formation or have decreased GSH stores and turnover rate. Many reported cases of APAP toxicity from RSTI involve patients who have factor(s) that influence their GSH supply or turnover, NAPQI production, or both, including infants with febrile illness who have received excessive dosing, chronic heavy ethanol users, and patients chronically taking CYP-inducing medications. The interplay of NAPQI and GSH may also be an important factor. For example, malnutrition is theorized to increase the risk of APAP toxicity³⁴²; however, both CYP2E1 activity⁵⁹ and GSH supply¹⁶³ are decreased in malnourished patients, and their relative impact on risk is unknown.

When there is concern about risk of toxicity after RSTI dosing, several approaches are suggested. The goal should be to select patients at risk based on dosing history and other risk factors and to then use limited laboratory testing to determine the need for NAC. A logical screening laboratory evaluation consists of determination of [APAP] and AST concentrations, with additional testing as indicated by these results and other clinical features. The objective is to identify the two conditions that warrant NAC therapy—remaining APAP yet to be metabolized and potentially serious hepatic injury.

Role of History and Physical Examination in Repeated Supratherapeutic Ingestions. The first consideration when evaluating a patient with a history of repeated supratherapeutic APAP dosing is the presence or absence of signs or symptoms of hepatotoxicity. Regardless of risk factors or dosing history, such findings should prompt treatment with NAC and laboratory evaluation. This is particularly important because most reported cases of serious toxicity after repeated dosing are symptomatic for more than 24 hours before diagnosis, and earlier treatment may improve outcome.

In asymptomatic patients, a reasonable approach is to perform laboratory evaluation for those who have ingested more than 200 mg/kg/day (or 10 g/day, whichever is less) in a 24 hours period or more than 150 mg/kg/day (or 6 g/day, whichever is less) in a 48 hours period.^{72,75,196} In children younger than 6 years of age, laboratory evaluation should be performed if the reported ingestion is more than 100 mg/kg/day during a 72 hours period or longer.

Several factors or characteristics place patients at higher risk for chronic APAP toxicity. High-risk factors that have been theorized include chronic heavy ethanol use; chronic ingestion of INH; febrile illnesses in infants and young children; and malnutrition, AIDS, or anorexia. In some cases, animal or basic science studies show evidence of increased risk, and in most cases, there have been multiple anecdotal reports of toxicity at therapeutic or slightly supratherapeutic doses. Whether these patients require a lower threshold for laboratory screening is unknown.

Role of Laboratory Evaluation in Repeated Supratherapeutic Ingestions. After a patient is determined to be at risk, an [APAP] and [AST] should be determined. These should be interpreted using the concept that a patient may be at risk of hepatotoxicity if there is evidence of hepatic injury (elevation of AST) or there remains enough APAP to produce further hepatic damage.

Using the strategy described here, patients with elevated [AST] are considered at risk, regardless of [APAP]. An [APAP] is useful in patients with normal [AST] as a tool to determine only whether sufficient APAP remains to lead to subsequent NAPQI formation and delayed hepatotoxicity. In many cases, [AST] is normal and [APAP] is below 10 µg/mL, obviating the need for NAC. If the [AST] is normal, then the patient should be considered at risk if [APAP] is 10 µg/mL or above. Higher thresholds for non-treatment, such as APAP below 30 µg/mL or AST twice as high as normal, have been suggested, but have not been studied and their sensitivity is unknown.

Patients who develop highly elevated [AST] after chronic APAP overdose should be treated and further evaluated with laboratory tests to assess hepatotoxicity and prognosis (creatinine, PT, INR, pH, phosphate, and lactate). Initial elevations of INR or creatinine may be markers of poor prognosis in APAP RSTI.⁴

The measurement of APAP protein adducts in urine has been described and theoretically could quantify NAPQI production in the liver. It has been suggested that adduct concentrations may identify APAP-induced hepatotoxicity in undifferentiated patients with elevated [AST]; however, adducts are elevated after both therapeutic and RSTI APAP ingestions and a clear defining value has not been determined.¹³³ In addition, the test remains largely unavailable and has been insufficiently studied.^{78,149,218} Several other biomarkers, including miRNA-122 and acetylated HMGB-1, have been tested in acute overdoses, but their utility in RSTI is unclear.

Patients who are identified as at risk, with either an elevated [AST] or an elevated [APAP], should be treated with NAC.

Risk Determination Following Acetaminophen Exposure in Children

Serious hepatotoxicity or death after acute APAP overdose is extremely rare in children.^{261,315} Predominant theories⁵ for resistance to toxicity include a relative hepatoprotection in children because of increased sulfation capacity²⁰⁷ or differences in the characteristics of children poisonings, including smaller ingested doses, overestimation of liquid doses, and unique formulations (pediatric elixirs that contain propylene glycol may result in decreased toxicity due to inhibition of CYP2E1).^{158,317} This has led some to suggest higher screening values and a higher nomogram line for children.³⁵ However, no significant change in NAPQI production has been demonstrated in children, and a more liberal approach to children's acute APAP ingestions has been inadequately studied and is not recommended. After repeated supratherapeutic APAP dosing, there is no evidence that children are relatively protected. Hepatic injury after therapeutic APAP is likely exceedingly rare in children.¹⁷⁹ However, infants and children with acute febrile illnesses comprise one of the few groups in which toxicity after repeated excessive dosing is well described.²⁴⁶ Common sources of dosing errors include substitution of adult for pediatric preparations; overzealous dosing by amount or frequency in attempts to maximize effect, and failure to read the label and dose carefully.^{8,246} Age younger than 2 years is an independent risk factor for development of toxicity.¹⁵⁶ These rare cases of toxicity in febrile children with repeated supratherapeutic dosing may simply reflect that these children constitute the most common setting for pediatric APAP use and that children are at greater relative risk for excessive dosing because of their size. Although logically one can argue that inflammatory oxidant stress and short-term fasting during febrile infectious illnesses affect oxidative drug metabolism and decrease GSH supply, these relationships are complex and not well defined. Of the reported cases of repeated supratherapeutic APAP dosing in children with hepatic injury, the cause was likely an isolated infectious illness in some, APAP in others, and a combination of the two in still others.

Risk Determination Following Acetaminophen Exposure in Pregnancy

The initial risk of toxicity in a pregnant woman is similar to that of a nonpregnant patient with a few exceptions. Little evidence suggests that any alteration of the treatment line is necessary. In fact, there are no reported cases of fetal or maternal toxicity in women with [APAP] below the treatment line²⁰³ or in those treated with NAC within 10 hours of an acute ingestion.²⁵⁵ However, there is controversy in assessing the risk of fetal toxicity after the mother has been determined to be at risk. To better understand the issues, a review of maternal–fetal physiology and pharmacokinetics related to APAP and NAC is necessary.

APAP is capable of crossing the human placenta,^{188,223,256} and APAP may be present in concentrations similar to maternal serum concentrations within hours after ingestion.^{223,256} Fetal metabolism of APAP probably is inefficient but is not completely understood. Fetal sulfation and oxidative metabolism of APAP are slower than in adults, and glucuronidation is undetectable until 23 weeks of gestation.²⁵⁷ CYP enzymes that are capable of oxidizing APAP are present in the fetus as early as 18 weeks gestation.²⁵⁷ However, the activity of these enzymes is less than 10% that of adult enzymes at 18 weeks gestation and increases to only 20% activity at 23 weeks.²⁵⁷ How the opposing forces of decreased overall metabolism of APAP and decreased NAPQI formation impact fetal risk is unclear.

The mechanism of fetal risk in women with APAP toxicity remains controversial. The degree of fetal toxicity that is attributable to fetal metabolism of APAP or to maternal illness is unclear. In clinical case series, the majority of pregnant women who overdose on APAP have uneventful pregnancies.^{203,255} Pregnant women who develop APAP toxicity in the first trimester have an increased risk of spontaneous abortion,²⁵⁵ fetal demise is described in the second trimester,³¹⁸ and those who develop APAP toxicity in the third trimester have a potential risk of fetal hepatotoxicity because of fetal metabolism. However, reports of third-trimester fetal hepatotoxicity are rare^{203,255} and are only associated with severe maternal toxicity.^{255,331} The factors associated with poor fetal outcome after a large APAP overdose are delayed treatment with NAC and young gestational age.

The decision to treat a pregnant woman with NAC requires consideration of what is known about the efficacy and beneficial effects as well as the adverse events of NAC for both the fetus and the mother. Every indication suggests that NAC is both safe and effective in treating the mother,²⁵⁵ but there are inadequate data to evaluate efficacy in the fetus, although fetal outcome has generally been excellent after maternal treatment with NAC.²⁵⁵ Given that NAC has been safely used in many pregnancies^{203,255} and fetal mortality is linked to delays to treatment, NAC should be initiated in pregnant women who meet the same criteria as nonpregnant patients. The necessary length of NAC therapy is difficult to determine. The 20 hour intravenous protocol probably is the most commonly recommended NAC protocol used for pregnant women worldwide; however, there is a paucity of published experience supporting NAC treatment courses shorter than the oral 72 hour protocol (Chap. 31).^{203,255}

Ethanol and Risk Determination

The effects of ethanol on APAP toxicity are complex and are best described by clearly separating experimental animal data

from actual human overdose experience, acute ethanol use from chronic heavy ethanol use or alcoholism, and single from repeated supratherapeutic APAP dosing. Ethanol use itself is difficult to define and many studies used different definitions. For the purpose of this section, the term chronic heavy ethanol use is defined as a person who ingests a mean of greater than two to three standard ethanol-containing drinks per day.²⁷⁶ Moderate ethanol use is defined as a mean of one to two standard ethanol-containing beverages per day. The term alcoholic will be used to define people whom either self-define as alcoholics or are identified as an alcoholic by the CAGE questionnaire, the Michigan Alcohol Screening Test, or similar screen.^{77,171,173}

Although not entirely consistent, both animal and human data suggest that acute ethanol coingestion with APAP may be hepatoprotective. Ethanol coingestion decreases NAPQI formation presumably by inhibiting CYP2E1 in both humans^{321,322} and animals.^{271,322} In large retrospective evaluations of overdoses, acute ethanol ingestion independently decreases the risk of severe hepatotoxicity in chronic heavy ethanol users²⁷⁶ and in nonchronic heavy ethanol users,²⁹³ but did not significantly decrease the risk of hepatotoxicity (ALT > 1000 IU/L) in a smaller prospective study.³³⁶

However, chronic ethanol administration increases the risk of hepatotoxicity from APAP dosing in animals.^{325,356} This may be a consequence of increased NAPQI formation due to induction of CYP2E1 metabolism once the ethanol is metabolized³¹⁹ or decreased mitochondrial GSH supply or regeneration.³⁵⁶

After acute APAP overdose, chronic heavy alcohol users who have not coingested ethanol may be at a slightly increased risk; however, this elevated risk appears to be of little clinical importance given the sensitivity of the treatment line.²⁹⁸ There is no credible evidence that chronic heavy alcohol use should alter the approach after an acute APAP overdose using the treatment line. In fact, the treatment line was developed with clinical data that included chronic heavy ethanol users.^{246,262} Given the paucity of data linking chronic heavy ethanol use to nomogram failures, it appears that the treatment line is adequately sensitive for screening after an acute APAP overdose, regardless of the patient's history of chronic heavy ethanol use.

The relationship between chronic heavy ethanol use and chronic APAP use is complex. Hepatotoxicity has been sporadically reported in patients with chronic heavy ethanol use after repeated supratherapeutic APAP dosing. Complicating these reports are the clinical challenges of obtaining accurate histories in chronic heavy ethanol users, failure to exclude non-APAP causes of hepatotoxicity, and other factors. Alcoholics are at higher risk of both using supratherapeutic doses of APAP and using combinations of multiple APAP-containing products.²⁸³ In contrast, prospective evidence demonstrates minimal risk of hepatotoxicity in alcoholic patients who ingest therapeutic doses of APAP.^{17,132,171,173} In prospective trials of ingestion of 4 g/day of APAP or placebo in chronic moderate to heavy ethanol users for up to 10 days, no clinically relevant increases in AST versus placebo have been identified.^{17,77,132,171,173} However, it should be noted that, in studies involving persons who abuse alcohol, mild AST elevations (< 120 IU/L) were noted in 40% of both study and controls, and more significant increases (> 120 IU/L, or three times normal) were noted in 4% to 6% of participants.^{171,173} In addition, in all studies, a small group of patients developed significant increases in aminotransferases, but most were unchanged. Patients who develop elevated aminotransferases after therapeutic dosing who are then rechallenged with additional APAP develop similar [AST] increases,¹³² implying that individual factors are likely more important than the chronic heavy ethanol use itself.

CYP Inducers and Risk Determination

Inducers of the CYP enzymes have long been theorized to increase the risk of toxicity from APAP because of a proportionally increased production of NAPQI. It is now clear that APAP is metabolized to NAPQI largely by CYP2E1^{130,198} and that only induction of this specific enzyme is likely to increase the risk of hepatotoxicity.

Although ethanol and INH are known inducers of CYP2E1, there is no evidence that the clinical approach to these patients should be altered. Similarly, several other medications, including phenytoin, carbamazepine, and phenobarbital, are theorized to increase APAP toxicity because of nonspecific CYP induction activity. None of these anticonvulsants induces CYP2E1, although there is some evidence that they increase NAPQI formation in cultured human hepatocyte and animal models, possibly through inhibition of glucuronidation.^{87,211} However, clinical experience suggests that there is no need to change the approach to these patients.

Assessing Actual Toxicity: Critical Components of the Diagnostic Approach

Initial Testing. The [APAP] should be measured in patients with acute APAP overdose and no evident hepatotoxicity, but no other initial laboratory assessment is required. AST concentration should be measured in patients who are considered to be at risk for APAP toxicity according to the nomogram or history (in the case of repeated supratherapeutic dosing) or in those suspected of already having mild hepatotoxicity by history and physical examination.

Unless evidence of serious hepatotoxicity is present, [AST] is a sufficient indication of hepatic conditions, and no additional testing is initially needed. Death of hepatocytes, resulting in release of measurable hepatic enzymes, precedes all

cases of serious hepatic dysfunction. Mild renal toxicity may rarely occur without hepatotoxicity⁴⁰; however, at least minimal elevation of [AST] generally precedes evidence of clinically significant nephrotoxicity.^{3,51} Exceptions are rare,^{40,161} and routine screening of renal function in the absence of elevated [AST] is probably unnecessary.

APAP overdose may lead to minor prolongation of PT even without causing hepatotoxicity.³⁴³ This most commonly occurs between 4 and 24 hours following ingestion and may be a result of NAPQI-related inhibition of vitamin K–dependent γ -carboxylation of factors II, VII, IX, and X.^{316,343} These minor prolongations (resulting PT usually is less than twice control) are rarely clinically relevant, are not evidence of hepatotoxicity, and should not be used as prognostic factors or indications for NAC treatment. In fact, treatment with NAC may also prolong PT^{150,167} by interfering with the PT assay, by reversing an APAP/NAPQI effect,³¹⁶ or by direct NAC effects.³¹⁶

Ongoing Monitoring and Testing. If no initial elevation of [AST] is noted, then repeated determination of [AST] alone—without other biochemical testing—is sufficient to exclude the development of hepatotoxicity. [AST] should be determined at the end of the protocol (eg, at 21 hours if using the standard intravenous protocol) or every 24 hours if using a longer protocol. If an elevated [AST] is noted, then PT and INR and creatinine should be measured and repeated every 24 hours or more frequently if clinically indicated. Results of other hepatic tests, such as GGT, alkaline phosphatase, lactate dehydrogenase, and bilirubin, which are useful when determining the cause of hepatic abnormalities, will be abnormal in cases of serious APAP-induced hepatotoxicity but provide little additional useful information if the cause is certain ([Chap. 23](#)).

If evidence of hepatic failure is noted, then careful monitoring of blood glucose, pH, PT, INR, creatinine, lactate, and phosphate concentrations are important in assessing extrahepatic organ toxicity and are vital in assessing hepatic function and the patient's potential need for hepatic transplant (see Assessing Prognosis). In addition, meticulous bedside evaluation is necessary to determine and document vital signs, neurologic status, and evidence of bleeding. Many additional tests may be useful in the setting of hepatic failure based on clinical condition and local protocols. Testing for other rare APAP-associated conditions by electrocardiography, lipase determination, or other studies should be performed on a case-by-case basis only.

MANAGEMENT

Gastrointestinal Decontamination

In cases of very early presentation or coingestion of xenobiotics that delay gastrointestinal (GI) absorption, gastric emptying may be appropriate for some patients. In general, however, gastric emptying is not appropriate for patients with isolated APAP overdose because of the very rapid GI absorption of APAP and the availability of an effective and safe antidote.

Administration of activated charcoal (AC) shortly following APAP ingestion may decrease the number of patients who have an [APAP] above the treatment line.⁴⁷ Although AC is most effective when given within the first 1 to 2 hours following APAP ingestion, it may be reasonable to consider AC at later times provided there are no contraindications.^{306,307}

Interactions between AC and orally administered NAC are likely clinically unimportant. In the majority of cases, there should be no interaction because GI absorption of APAP, and therefore the necessity to give AC, is complete by 4 hours following ingestion, and NAC typically is administered between 4 and 8 hours following ingestion. As a result, there is generally no difficulty separating the doses. If delayed or repeated AC dosing is indicated because of suspected delayed absorption or coingestants, then a strategy using an intravenous NAC protocol should be considered. Alternatively, oral NAC and AC doses may be separated by 1 to 2 hours, with NAC given the priority for the first dose because time to administration of NAC correlates with risk of hepatotoxicity.^{293,299} NAC is absorbed high in the GI tract and is not likely to interact with AC if they are not administered simultaneously.

Supportive Care

General supportive care consists primarily of controlling nausea and vomiting and managing the hepatic injury, acute kidney injury, and other manifestations. Treatment of these problems is based on general principles and is not APAP dependent. Discussion of the management of hepatic failure is clearly beyond the scope of this chapter, but certain aspects deserve mention. Monitoring for and treatment of hypoglycemia are critical because hypoglycemia is one of the most readily treatable of the life-threatening effects of hepatic failure. If adequate viable hepatocytes are present, vitamin K may produce some improvement in coagulopathy; thus, trial dosing is logical as hepatic injury develops and as it resolves. Administration of fresh-frozen plasma (FFP) and prothrombin complex concentrates (PCCs) should be based on specific indications rather than PT and INR alone. Hemorrhage is rare in APAP-induced hepatic failure and correction of coagulopathy should only be necessary for procedures and life-threatening bleeding. Supportive therapy for cerebral edema, including cooling, hypertonic saline, elevation of the head, and support of the cerebral perfusion pressure, are all

indicated.

Antidotal Therapy with N-Acetylcysteine. Mechanism of action of N-acetylcysteine. Conceptually, it is helpful to think of NAC as serving three distinct roles. During the metabolism of APAP to NAPQI, NAC prevents toxicity by limiting the formation of NAPQI. More importantly, it increases the capacity to detoxify NAPQI that is formed (Fig. 35–1). In fulminant hepatic failure, NAC treats toxicity through nonspecific mechanisms that preserve multiorgan function. A complete discussion of NAC can be found in Antidotes in Depth: A3. A brief review follows.

NAC prevents toxicity mostly by serving as a GSH precursor¹⁷⁸ and also as a GSH substitute,²⁸⁶ combining with NAPQI and being converted to cysteine and mercaptate conjugates.⁴⁸ NAC may also lead to increased substrate for nontoxic sulfation, allowing less metabolism by oxidation to NAPQI.²⁹⁴ Each of these preventive mechanisms must be in place early, and none is of benefit after NAPQI has initiated cell injury. Time is required to saturate nontoxic metabolism, form excessive NAPQI, deplete GSH, and overcome GSH production; thus there is a window of opportunity after exposure to an APAP overdose during which NAC can be initiated before the onset of hepatic injury without any loss of efficacy. Based on large clinical trials, it appears that NAC efficacy is nearly complete as long as it is initiated within 6 to 8 hours of an acute overdose.^{159,293,299,300} However, the relationship between the time to administration of NAC and the risk of hepatotoxicity should be considered a continuous variable. The risk of hepatotoxicity begins to increase at 6 hours for patients with very high [APAP] and is closer to 8 hours for patients with [APAP] just over the treatment line.^{293,308} For this reason, NAC therapy should not be unnecessarily delayed past 6 hours if it can be safely administered earlier.

Several observations illustrate the effectiveness of NAC by other mechanisms of action even after NAPQI formation and binding. NAC actually reverses NAPQI oxidation in both a mouse model⁶⁵ and an in vitro human hepatocyte model,¹⁹⁷ and even after cell injury is initiated, NAC may diminish hepatocyte injury.⁴⁴ Most significantly, a prospective, randomized trial found that even after fulminant hepatic failure was evident, intravenous NAC diminished the need for vasopressors and the incidences of cerebral edema and death.¹⁵⁷ In this study, despite improved organ function and survival in the NAC-treated group, there was no apparent difference in the degree of hepatic injury, implying that much of the benefit of NAC in this setting may not be derived from hepatic effects. Whether based on its nonspecific antioxidant effects, its increase in oxygen delivery and utilization, its ability to enhance GSH supply and mitochondrial ATP production, or its role in mediating microvascular tone,^{82,127,152,263,305,330,331} NAC improves function in several organs affected by multisystem failure.^{82,328} In fact, NAC may preserve cerebral blood flow and perfusion in the setting of cerebral edema³⁴⁰ more effectively than traditional therapies such as mannitol and hyperventilation, which may actually be detrimental.

Although NAC has a defined role in preventing and treating APAP-induced hepatic injury, its role in treating APAP-induced acute kidney injury is less clear. When used early after ingestion in animals, NAC produces a small reduction in kidney injury.^{215,295} In retrospective reviews of human data, NAC has had little effect on kidney injury⁸⁰ but does not appear to be harmful.²¹⁷ However, few data are available to recommend NAC therapy in treating isolated acute kidney injury or acute kidney injury after resolution of hepatic injury.

N-acetylcysteine administration. NAC may be administered via the oral or intravenous routes and in protocols that have historically varied in length. The two most common regimens are a 21 hour intravenous infusion and a 72 hour oral dosing protocol. However, the concept of a set-length protocol is obsolete. Conceptually, practitioners should start NAC when the patient is at risk of toxicity, continue NAC while the patient remains at risk or has hepatotoxicity, and stop NAC when that risk or toxicity is gone. Most institutions now use either oral or intravenous NAC in a variable length protocol, using indicators of patient toxicity rather than a set protocol length.¹³¹ These are described at length in Antidotes in Depth: A3.

With the exception of established hepatic failure, for which only the intravenous route has been investigated,¹⁵⁷ the intravenous and oral routes of NAC are equally efficacious in preventing or treating APAP toxicity.^{46,241} The decision to treat with intravenous or oral dosing is complex and is described in Antidotes in Depth: A3. In brief, whereas intravenous NAC has been associated with rare but severe anaphylactoid reactions and medication errors,¹²⁹ oral NAC is associated with a greater than 20% risk of vomiting. There are three scenarios in which intravenous NAC is generally recommended: (1) APAP toxicity in pregnant women, (2) APAP-induced hepatic failure, and (3) intractable vomiting preventing oral treatment.

Duration of N-acetylcysteine treatment. Known mechanisms of action and the observation that all studied durations of NAC are effective when started within 8 hours⁴⁶ suggest that all courses of treatment currently published are effective when NAC is used for its early preventive actions. There is some suggestion that there may be a slightly decreased risk of hepatotoxicity if intravenous NAC, as opposed to oral NAC, is used before 10 hours after the ingestion, but this remains controversial.³⁵⁰ Results from use of the traditional 21 hour intravenous NAC protocol, the 48 hour and 36 hour intravenous NAC protocols studied in the United States,²⁹⁶ one 20 hour protocol,³⁵¹ and other “short-course” dosing protocols^{29,28,347} indicate that those therapies are likely safe and effective in these low-risk scenarios.^{314,352}

It is important to realize that even in low-risk patients (those treated within 8 hours), regardless of the protocol length (21, 36, 48, or 72 hours) or route of delivery, NAC therapy should be continued until APAP metabolism is complete (the [APAP] is below detection) and there are no signs of hepatotoxicity. With this concept in mind, it may seem reasonable to

shorten a set course of NAC if the patient is low risk and the above criteria are met ([APAP] undetectable, [AST] normal, PT/INR less than twice normal, and no encephalopathy).^{29,74,293} This approach is conceptually reasonable and is aimed at decreasing unnecessary therapy as there is no evidence that prolonged NAC is helpful and there is one animal study that suggests that prolonged NAC may inhibit hepatic recovery,³⁴⁹ however, adequate studies have not definitively confirmed its safety.^{285,293}

NAC therapy should be continued beyond the prescribed “protocol length” if there is evidence of hepatic injury ([AST] significantly above normal or PT/INR > twice normal or encephalopathy is present) or APAP metabolism is incomplete ([APAP] detectable). This likely will not be an issue in the vast majority of cases because the aminotransferases of approximately one-half of all NAC-treated patients with [APAP] above the treatment line will remain below 100 IU/L.³⁰⁰ The intravenous NAC dosing protocol that has proved beneficial in patients with hepatic failure is the same initial dosing as the traditional intravenous protocol but with the third intravenous infusion continued until there is resolution of hepatic failure. These observations suggest that rather than a single duration of therapy for all patients, it is appropriate to extend treatment protocols based on the clinical course of the patient.⁷⁴

After NAC therapy is extended beyond a set-length protocol, the decision to discontinue therapy should be entirely based on the patient’s condition. For patients who develop hepatic failure, intravenous NAC is continued until the PT or INR is below twice the rate of normal and encephalopathy, if present, is resolved.¹⁹⁶ For patients without hepatic failure but with elevated [AST], NAC is often continued until all hepatic abnormalities resolve (eg, [AST] is decreasing and < 1000 IU/L).

Assessing Risk of Hepatotoxicity. Most patients who are treated with NAC do not develop hepatotoxicity and have short hospital stays, whereas a small percentage develop hepatotoxicity and an even smaller group develop hepatic failure. It may be helpful to predict the risk of hepatotoxicity based on initial findings to direct the intensity of monitoring and therapy (see Dose Adjustment) and patient disposition.

In general, both the time from ingestion to the initiation of NAC and [APAP] are directly proportional to the patient’s risk of developing hepatotoxicity and hepatic failure.^{274,293,299} Even in patients treated early after their ingestion, their risk of hepatotoxicity is significant if their [APAP] is highly elevated.²⁵⁹ Using these principles, a nomogram has been produced that may be used to determine the risk of hepatotoxicity on patient arrival. Unfortunately, this only predicts the risk of a peak aminotransferase concentration above 1000 IU/L and has not been studied to determine the risk of death or need for transplantation. In addition, the multiplicative sum of [AST] (or [ALT]) and [APAP] has also been studied to predict hepatotoxicity, but requires validation.²⁹² Acetylated HMGB-1 is a promising biomarker for detecting patients who will go on to have severe hepatic failure and may be useful for early prognostication.¹¹ Initial human studies, [acet-HMGB-1] increased only in patients who later met the King’s College Criteria for hepatic transplant, received a transplant, or died.¹¹ These results are promising and require validation and further study.

Dose Adjustment. In rare cases, patients with massive ingestions with or without antimuscarinic co-ingestants may have highly elevated [APAP] for prolonged periods or secondary elevations of the [APAP].^{86,88,134,282,332} Several of these patients have developed hepatotoxicity despite early (< 6 hours) intravenous NAC therapy,^{88,134,282,332} raising the question of whether the traditional intravenous NAC infusion (6.25 mg/kg/h) provides enough NAC for these rare patients with late elevated [APAP] or massive ingestions. Several theoretical solutions have been noted, but none are tested and a consensus opinion on optimal therapy does not exist. In these rare patients, consideration should be given to treating with greater amounts of NAC once prolonged, massive [APAP] are evident.^{282,303} No data exist to determine which, if any, alternative NAC dosing strategy is superior. For a detailed description of increased dosing for massive ingestions, highly elevated [APAP], and prolonged elevations of [APAP], see Antidotes in Depth: A3. A brief synopsis is described below and is based on calculations that use logical inferences, but none of these concepts has been studied and should not be considered standard therapy. The described dosing protocol has little risk, but has unproven benefit, and should be used with caution in extreme clinical cases:²⁶⁰

1. If the ingestion is between 16 and 32 g or the initial [APAP] is between the “300-line” and the “500-line,” then consider using 12.5 mg/kg/h as the 16 hour infusion rate.
2. If the ingestion is between 32 and 48 g or the initial [APAP] is above the “500-line,” then consider using 18.75 mg/kg/h as the 16 hour infusion rate.
3. If the ingestion is greater than 48 g, then consider using 25 mg/kg/h as the 16 hour infusion rate.
4. If the [APAP] at 20 hours or later is 25 to 50 µg/mL, then use 12.5 mg/kg/h as the continuous infusion. If the [APAP] at 20 hours or later is > 50 µg/mL, then use 18.75 mg/kg/h as the continuous infusion.

An alternative approach equally logical, but also unstudied, is to combine both the oral NAC protocol with the intravenous NAC protocol. This method provides both an additional bolus dose (290 mg/kg), as well as 23.75 mg/kg/h as the continuous infusion.

Hepatic Transplantation. Hepatic transplantation may increase survival for a select group of severely ill patients who have APAP-induced fulminant hepatic failure.^{196,226} Tremendous improvements in transplantation and supportive hepatic

care have increased immediate survival rates after hepatic transplantation to 69% to 78% with 3- to 5-year survival rates of 54% to 66%,^{26,64,160,196,288} respectively, which is similar to transplant survival for other causes of acute hepatic failure. Patients who meet criteria for transplant but do not receive an organ have had survival rates ranging from 5% to 17%,^{24,25,176,196,209,227} but higher survival rates have recently been reported.²⁷⁵

Concerns that patients who receive transplants for APAP-induced fulminant hepatic failure will have lower survival rates and be unable to maintain post-transplant medication regimens have resulted in the majority of patients not being listed for transplant.²⁶ However, those who meet psychosocial criteria for transplantation have high rates of survival,^{26,64,196} and 12% later die from intentional rejection or suicide attempts.²⁶ Techniques that allow subtotal hepatectomy with transplantation and eventual weaning of immunosuppressants are promising and may allow for higher rates of transplantation.¹⁹³

Assessing Prognosis. Determining a patient's prognosis and predicting patients who require transplantation early in the course of the disease is an important area of current research.

The most commonly used indicator of the need for immediate transplantation is the King's College Criteria (KCC; [Table 35–1](#)), which was developed and validated on patients with APAP-induced fulminant hepatic failure. The criteria include a serum pH below 7.30 after fluid resuscitation or the combination of creatinine above 3.3 mg/dL, PT above 100 sec (INR > 6.5 is commonly used), and grade III or IV encephalopathy. The survival rate of patients who meet the KCC but do not receive an organ remains below 20% in most centers.^{16,26,60,67,68,227} Significantly higher survival rates in patients meeting transplant criteria have recently been reported and may be due to the utilization of prolonged NAC therapy and improved supportive care for patients with acute hepatic failure.^{110,275}

TABLE 35–1. King's College Criteria for Predicting Need for Hepatic Transplant

Either of the following predicts a survival rate < 20% and the need for immediate transplantation, if available and appropriate:

1. Arterial pH < 7.3 or lactate > 3.0 mmol/L after fluid resuscitation

OR

2. All of the following:

- a. Creatinine > 3.3 mg/dL
- b. Prothrombin time > 100 sec (or international normalized ratio > 6.5)
- c. Grade III or IV encephalopathy (somnolence to stupor; responsive to verbal stimuli; confusion; gross disorientation)

When determining the KCC, interpretation of PT and INR must include awareness of concurrent NAC therapy as well as therapy with vitamin K, PCCs, factor VII, and FFP. The use of vitamin K, if effective, implies that transplant may be unnecessary because viable liver remains. If vitamin K is ineffective, then PT and INR can be used, as discussed in the previous paragraph. Transfusion of exogenous clotting factors, such as FFP or PCCs, alters interpretation because improvement in PT and INR may not indicate improvement in hepatic function. The prognostic importance of monitoring PT and INR in this setting suggests that FFP should be given only with evidence of bleeding, with risk of bleeding from known concomitant trauma, or before invasive procedures and not based merely on the PT and INR.

A lactate concentration above 3.5 mmol/L at a median of 55 hours after APAP ingestion or lactate concentration above 3.0 mmol/L after fluid resuscitation is shown to be both sensitive and a specific predictor of patient death without transplant.^{25,71} Additional studies confirmed lactate as an independent predictor of prognosis but suggest that it does not add significantly to the KCC.^{60,279} Others have confirmed a lower specificity than initially reported.^{110,279} Using a higher cutoff (> 4.7 mmol/L) has a high sensitivity (98%) and NPV (95%), but moderate specificity (58%) for determining death or transplant.^{60,279}

Unfortunately, patients often meet the KCC and lactate criteria quite late in their course of disease, so these criteria are not useful as early predictors or as standards for transfer to a facility that performs hepatic transplant. General factors that are associated with increased mortality include unintentional overdose, repeated supratherapeutic dosing, and delays to receiving NAC therapy.^{69,70} Additional predictors of severity of hepatic toxicity in patients treated with NAC include a rapid doubling of [AST] or [ALT] (doubling < 8 hours)¹¹⁷ and [AST] or [ALT] reaching 1000 IU/L within 20 hours of NAC treatment.¹¹⁷ Several attempts at determining early predictors of death or the need for transplant have proven to be no more effective than the KCC, including serum phosphate (day 2),^{24,277} Model for Endstage Liver Disease (MELD) score of 32 or above,^{60,192,278} serum Gc-globulin,^{183,273} factor V concentration,^{141,234} factor VIII:V ratio,^{41,234} worsening day 4 PT and INR,¹²⁶ and PT (in seconds) larger than the number of hours since ingestion.²²²

An Acute Physiology and Chronic Health Evaluation (APACHE) II score above 15 in isolated APAP ingestions may be as specific as the above KCC criteria and slightly more sensitive.^{60,209} These criteria may be beneficial in determining whether to transfer a patient to a transplant center because the score is easily calculated, is sensitive, and is available within the first day of admission; however, confounders such as coingestants may decrease its utility. Furthermore, an APACHE III score above 60 may be helpful in identifying additional patients with multiorgan dysfunction who may require transplantation.²⁶

Several measurements of organ failure have been postulated as indications for transfer to a regional transplant center from a non-transplant facility. The Sequential Organ Failure Assessment (SOFA) score higher than 7 within the first 96 hours after acute overdose and evidence of the systemic inflammatory response syndrome both predict increased mortality (a 100% sensitivity and a 74% to 77% specificity).⁶⁷ Conversely, a patient with a SOFA score of 7 or less during the first 96 hours after acute overdose has a low mortality (< 2%), low risk of requiring renal replacement therapy (< 4%), and low risk of requiring intracranial pressure monitoring (< 2%).⁶⁷ Additionally, SOFA score below 6 after repeated supratherapeutic ingestion of APAP predicts survival and a low risk of the need for renal replacement therapy or intracranial pressure monitoring (< 10%).⁶⁸

The KCC, APACHE II, SOFA, and MELD scores, as well as serum lactate 12 hours after admission, have been recently compared and may all be helpful in making patient decisions.⁶⁰ The MELD score (> 32) and lactate concentration (> 4.7 mmol/L) are the most sensitive to determine death or transplant in APAP-induced hepatic failure. These scores may be helpful in predicting death or the need for a higher level of care (Table 35–2), whereas, the most specific scores are the KCC, APACHE II (> 11), and SOFA (> 12). These may be most helpful in determining patients who need transplant (Table 35–2).

TABLE 35–2. Prediction of Death or Transplant in 125 Patients with APAP Induced Liver Failure⁶⁰

Score	Sensitivity (%)	Specificity (%)	PPV	NPV
King's College Criteria	47	83	0.70	0.65
Acute Physiology and Chronic Health Evaluation II (> 12)	67	76	0.69	0.75
Sequential Organ Failure Assessment (> 12)	67	80	0.74	0.74
Model for Endstage Liver Disease (> 32)	89	25	0.49	0.77
Lactate (> 3.3 mmol/L)	91	52	0.69	0.83

NPV = negative predictive value; PPV = positive predictive value.

Acetylated HMGB-1 is a biomarker that is released as a proinflammatory mediator from monocytes and macrophages and in one small study was highly correlated with patients that met transplantation criteria or died.¹¹ These studies are promising, but will require validation before clinical use is postulated.

Additional Elimination Techniques

Several clinical scenarios may benefit from increasing clearance of APAP from the body. Indications early after APAP overdose may include patients with exceedingly high [APAP] who are at high risk of hepatotoxicity despite NAC therapy as well as those with hyperlactatemia and metabolic acidosis. Later in the course of APAP toxicity, elimination techniques may be used to remove elevated [APAP] in patients who are imminently receiving a hepatic transplant or for removal of toxins related to hepatic failure (Table 35–3).

TABLE 35–3. Management of Patients at Risk for APAP Toxicity

1. Start NAC on patients at risk of hepatotoxicity:
 - a. In acute overdose, plot a single [APAP] on the nomogram using the earliest possible time of ingestion. If the plot is over the treatment line, initiate NAC
 - i. If patient is at risk for massive and prolonged exposure to [APAP] (eg, ingestion > 30 g and/or co-ingested antimuscarinics), consider higher-dose NAC therapy
 - b. In RSTI, if [AST] is elevated, initiate NAC

- c. If AST is normal and [APAP] > 10 µg/mL, initiate NAC
- d. If patient has evidence of liver failure (encephalopathy, INR/prothrombin time elevation), consider transfer to liver transplant center
2. Initiate IV NAC or rarely oral NAC.
3. Laboratory evaluation at 20 to 24 hours (20 hours if IV NAC is used, 20–24 hours if PO NAC is used). Continue NAC on patients who remain at risk of toxicity or have developed toxicity.
 - a. If patient remains at risk of toxicity ([APAP] detectable) or if toxicity is evident ([AST] elevated), then continue NAC for 16–24 hours more
 - b. If [APAP] at 20 to 24 hours is very elevated, consider higher dose NAC therapy
4. Continue laboratory evaluation every 16–24 hours.
5. Stop NAC when the patient is no longer at risk of toxicity:
 - a. If liver failure was evident, continue NAC until INR < 2, encephalopathy resolves, and [APAP] is undetectable
 - b. If liver failure was not evident, but [AST] was elevated, then continue NAC until [AST] has decreased to < 1000 IU/L, no evidence of liver failure, and [APAP] is undetectable

AST = aspartate aminotransferase; INR = international normalized ratio; IV = intravenous; NAC = N-acetylcysteine; PO = oral; RSTI = repeated supratherapeutic ingestion.

Hemodialysis. Both intermittent hemodialysis (HD) and continuous venovenous hemodialysis (CVVHD) increase elimination of APAP. HD has been used early after overdose to eliminate highly elevated [APAP], typically above 500 µg/mL,^{96,119,341} and in patients with slow clearance of [APAP] late after overdose.³⁴⁸ Clearance averages about 150 mL/min^{96,119,348} with blood flow of approximately 300 mL/min. In one case, HD removed approximately 2 g of APAP when the initial [APAP] was 103 µg/mL, and the amount that HD removes varies directly with the initial [APAP].^{96,348} HD reduces the APAP elimination half-life by approximately 50%^{119,229,348} and has an extraction ratio of 50% to 80%.^{119,346,348} HD also removes NAC and NAC infusion rates should be increased to 12.5 mg/kg/h (from 6.25 mg/kg/h) during HD.¹¹⁹

CVVHD has been described in one case³⁴¹ in which the continuous modality was used due to concerns of hypotension on intermittent HD. In 16 hours, CVVHD had an average clearance of 42.1 mL/min and removed about 24 g of APAP; ([APAP] at initiation of CVVHD was 1212 µg/mL).³⁴¹

Plasmapheresis and Plasma Exchange. Plasmapheresis removes small amounts (5%) of APAP with therapeutic dosing, but few data exist with regard to overdose.⁹⁷ Plasmapheresis may be useful in patients with acute liver failure to correct coagulopathy, but it does not reliably correct encephalopathy.²⁹⁰

Exchange transfusion was used in one 1.22 kg neonate who had a [APAP] of 75 µg/mL after maternal oral overdose and subsequent delivery.¹⁸² Exchange transfusion eliminated a portion of total APAP as evidenced by reduced [APAP] and rebound [APAP] after transfusion. For example, in one exchange of 210 mL blood (1.22-kg patient), the serum [APAP] decreased from 32 µg/mL to zero, then rebounded to 30 µg/mL.¹⁸²

Liver Dialysis. Liver dialysis devices include extracorporeal albumin dialysis (eg, molecular adsorbent recirculation system [MARS]), fractionated plasma separation and adsorption and single pass albumin dialysis (SPAD). The MARS system may be used as a bridge to transplantation, for hemodynamic stabilization prior to hepatic transplant, or as a bridge to spontaneous recovery in patients with APAP-induced hepatic failure. Although MARS improves encephalopathy,²⁶⁶ cerebral blood flow,²⁸⁰ hemodynamics (increases in SVR, MAP, and decreases in cardiac index {CI} and pulse {HR}),^{175,281} and intracranial pressure,³⁰⁴ a meta-analysis concluded that MARS has no effect on mortality in multiple cause acute liver failure.¹⁶² One report notes complete removal of APAP from the blood ([APAP] decreased from 40 µg/mL to 0 µg/mL from inflow to outflow) during MARS with rebound [APAP], suggesting that MARS may improve APAP clearance.¹²⁰

Prometheus may also be used as a bridge to transplantation, but is relatively unstudied in APAP induced acute hepatic failure. Prometheus produces higher clearance of ammonia than MARS, but does not improve hemodynamics.¹⁷⁵

SPAD is venovenous hemodialysis with a dialysate containing 4.4% albumin. SPAD may more effectively clear ammonia than MARS,²⁷² but there were no changes in hemodynamics or encephalopathy after therapy with SPAD in one study of patients with acute hepatic failure.¹⁵⁵

SUMMARY

- The decision to treat an acute APAP overdose requires plotting a single [APAP] onto the modified Rumack-Matthew

nomogram and treating patients with NAC if their [APAP] plots above the treatment line, or the “150-line.”

- Patients should be treated with NAC after RSTIs of APAP if their [AST] is greater than normal or their [APAP] is detectable.
- The King’s College Criteria identifies patients with high mortality and is an indication for evaluation for hepatic transplantation:
 - a. Arterial pH < 7.3 or lactate > 3.0 mmol/L after fluid resuscitation OR
 - b. All of the following:
 - i. Creatinine > 3.3 mg/dL
 - ii. PT > 100 sec (or INR > 6.5)
 - iii. Grade III or IV encephalopathy (somnolence to stupor; responsive to verbal stimuli; confusion; gross disorientation)
- NAC therapy should no longer be given as a set length protocol. Once NAC therapy is started, an informed decision should be made when to stop NAC, which requires an assessment of [AST] and [APAP], that the risk of developing toxicity is low ([APAP] is undetectable and [AST] is normal), and any toxicity that occurred has now resolved ([AST] has decreased and is near normal and there is no evidence of hepatic failure).

A3 ANTIDOTES IN DEPTH

N-Acetylcysteine

Robert G. Hendrickson and Mary Ann Howland

INTRODUCTION

N-acetylcysteine (NAC) is the cornerstone of therapy for patients with potentially lethal acetaminophen (APAP) overdoses. If administered early, NAC can then prevent APAP induced hepatotoxicity. If administered after the onset of hepatotoxicity, NAC improves outcomes and decreases mortality. NAC may also limit hepatotoxicity from other xenobiotics that result in glutathione depletion and free radical formation, such as cyclopeptide-containing mushrooms, carbon tetrachloride, chloroform, pennyroyal oil, clove oil, and possibly liver failure from chronic valproic acid use.³¹ Finally, NAC may be useful in the management of adults with fulminant hepatic failure caused by nontoxicologic etiologies.^{20,75,81,84,149}

HISTORY

Shortly after the first case of APAP hepatotoxicity was reported, Mitchell described the protective effect of glutathione.^{97,127} Prescott¹¹³ first suggested NAC for APAP poisoning in 1974. Early experiments demonstrated that NAC could prevent APAP-induced hepatotoxicity in mice and that the oral (PO) and intravenous (IV) routes were equally efficacious when treatment was initiated early after ingestion.¹⁰⁶ Several groups^{96,112,113,126} performed human research with oral and IV NAC in the 1970s. The US Food and Drug Administration (FDA) approved NAC for oral use in 1985 and for IV use in 2004.

PHARMACOLOGY

Chemistry

NAC is a thiol containing (R-SH) compound that is deacetylated to cysteine, an amino acid used intracellularly. The amino acids cysteine, glycine, and glutamate are used to synthesize glutathione.¹²³

Related Xenobiotics

Cysteamine, methionine, and NAC, which are all glutathione precursors or substitutes, have been used successfully to prevent hepatotoxicity, but cysteamine and methionine both produce more adverse effects than NAC, and methionine is less effective than NAC. Therefore, NAC has emerged as the preferred treatment.^{110,137,160,162}

Mechanism of Action

NAC has several distinct roles in the treatment of APAP poisoning. Early after ingestion when APAP is being metabolized to N-acetyl benzoquinoneimine (NAPQI), NAC prevents toxicity by rapidly detoxifying NAPQI. After hepatotoxicity is evident, NAC decreases toxicity through several nonspecific mechanisms, including free radical scavenging, increasing oxygen delivery, increased mitochondrial adenosine triphosphate (ATP) production, antioxidant effects, and alteration of microvascular tone.

NAC effectively prevents APAP induced hepatotoxicity if it is administered before glutathione stores are depleted to 30% of normal. This level of depletion occurs approximately 6 to 8 hours following toxic APAP ingestion.^{112,120} In this preventive role, NAC acts primarily as a precursor for the synthesis of glutathione.⁷⁷ The availability of cysteine is the rate-limiting step in the synthesis of glutathione, and NAC is effective in replenishing diminished supplies of both cysteine and glutathione. Additional minor mechanisms of NAC in preventing hepatotoxicity include acting as a substrate for sulfation,¹³⁹ as an intracellular glutathione substitute by directly binding to NAPQI,²⁹ and by enhancing the reduction of NAPQI to APAP.^{78,135}

After NAPQI covalently binds to hepatocytes and other tissues,¹²⁰ NAC modulates the subsequent cascade of inflammatory events in a variety of ways.⁵⁵ NAC may act directly as an antioxidant or as a precursor to glutathione. Glutathione protects cells against electrophilic compounds by acting as both a reducing agent and an antioxidant.¹²⁴ NAC improves oxygen delivery^{38,55,146,163,164} and utilization in extrahepatic organs such as the brain, heart, and kidney, probably by improving blood flow in the microvasculature, although the exact mechanism is unclear.^{83,133} In addition, NAC increases hepatic mitochondrial ATP production in mice¹²⁹ and demonstrates a suppressive action on macrophages, neutrophils, leukocyte endothelial cell adhesion, and cytokines.⁷⁵

Pharmacokinetics/Pharmacodynamics

Administered NAC is present in plasma in the reduced or oxidized state and is either free or bound to plasma proteins or with other thiols and SH groups to form mixed disulfides such as NAC–cysteine.¹¹¹ NAC has a relatively small volume of distribution (0.5 L/kg), and protein binding is 83%. NAC is metabolized to many sulfur containing compounds such as cysteine, glutathione, methionine, cystine, and disulfides, as well as conjugates of electrophilic compounds, that are not routinely measured.^{47,105,111} Thus, the pharmacodynamic study of NAC is complex. In addition, the pharmacokinetics of NAC are complicated based on whether total or free NAC is being measured.¹¹¹

Pharmacokinetics of Oral N-Acetylcysteine. Oral NAC is rapidly absorbed, but its bioavailability is low (10%–30%) because of significant first-pass metabolism.^{47,105,111} The mean time to peak serum concentration is 1.4 ± 0.7 hours. The mean elimination half-life is 2.5 ± 0.6 hours and is linear with increasing dose up to 3200 mg/m²/day given as a single daily dose. Inter-subject serum NAC concentrations vary tenfold.¹⁰⁵ Chronic administration leads to a decrease in plasma concentrations from a C_{\max} of 8.9 mg/L (55 μ mol/L) at the end of 1 month to 5.1 mg/L (31 μ mol/L) at the end of 6 months.¹⁰⁵

Conflicting in vitro^{30,73,127} and in vivo^{28,45,101,117} data regarding the concomitant use of PO NAC and activated charcoal suggest that the resultant bioavailability of NAC is either decreased or unchanged. This interaction is likely of limited clinical importance, and PO or IV NAC can be initiated without concern for activated charcoal interaction (**Chap. 35**).

Pharmacokinetics of IV N-Acetylcysteine. When only free NAC was analyzed, healthy volunteers given 600 mg IV NAC achieved peak serum NAC concentration of 49 mg/L (300 μ mol/L) with a half-life of 2.27 hours compared with a peak serum concentration of 2.6 mg/L (16 μ mol/L) after 600 mg PO.²⁴ Serum concentrations after IV administration of an initial loading dose of 150 mg/kg over 15 minutes reach approximately 500 mg/L (3075 μ mol/L).¹¹¹ A steady-state serum concentration of 35 mg/L (10–90 mg/L) is reached in approximately 12 hours with the standard IV protocol.¹¹¹ Approximately 30% is eliminated renally.

Once in the blood, IV and PO NAC have a similar half-life (2–2.5 hours). This half-life is increased in the setting of severe liver failure or end-stage kidney disease because of a reduction in clearance.^{67,100}

Intravenous vs. Oral Administration. As in the case of many issues related to APAP toxicity, the choice of PO versus IV NAC is complex. The available information suggests that each has advantages and disadvantages, and each may be more appropriate than the other in certain settings. Because no controlled studies have compared IV with PO NAC, conclusions about the relative benefit of each are largely speculative.

With the exception of fulminant hepatic failure, for which only the IV route has been investigated, IV and PO NAC administration are equally efficacious in treating patients with APAP toxicity.¹¹⁴ Some data suggest that IV NAC may be slightly more efficacious when given less than 12 hours after an overdose and that PO NAC is significantly more efficacious when given after 16 hours after overdose; however, this study compared patient groups that differed by decade of treatment and by country. It remains unclear if these differences are true or clinically relevant.^{114,172,173} In addition, any difference in outcome for patients who are treated after 16 hours almost certainly is related to the duration and total dose of NAC therapy rather than the route itself. The decision of which route to use should depend on the rate of adverse events, safety, availability, and ease of use. Efficacy should not be a consideration.

Safety is the best understood of these issues. Nausea and vomiting may occur in up to 20% of patients treated with PO NAC compared to 7% with IV NAC.⁵⁷ Diarrhea and headache are prevalent, but there is no credible evidence of more serious complications resulting from PO NAC. Reports of skin rash and unusual complications are rare.⁹⁷ In contrast, IV NAC is associated with a 14% to 18%⁷² rate of anaphylactoid reactions, although rates of 2% to 6% are reported in retrospective trials.^{63,68,168,175} Most of these reactions are mild and include rash, flushing, nausea, and vomiting.^{10,72,130,140,177} Anaphylactoid reactions may be severe in approximately 1% of cases^{72,94,176} and in rare instances may lead to hypotension and death.^{7,17,35,68,89,93,106,140,173,174} Anaphylactoid reactions are attributed to both the dose and concentration of NAC and are caused by a non IgE mediated release of histamine from mast cells and mononucleocytes.³² APAP inhibits mast cell histamine release; therefore, a higher APAP concentration at the time of NAC delivery decreases the risk of anaphylactoid reactions.^{32,166} The anaphylactoid reaction rate is decreased by using a more dilute NAC solution^{68,72,175} and by slowing NAC infusions in some studies.²⁸ In one prospective study, prolongation of the loading infusion from 15 to 60 minutes did not decrease the anaphylactoid rate significantly (from 18% to 14%).^{48,63,72,88}

Minor reactions, such as rash, generally do not require treatment, rarely recur, and do not preclude administration of subsequent NAC doses.^{11,140,175,178} Even when urticaria, angioedema, and respiratory symptoms develop, they usually are easily treated, and NAC can be subsequently restarted with a very low incidence of recurrence.^{11,108,130,178} Although proper dosing of IV NAC is very safe, it nevertheless must be considered less safe than PO NAC because of the possibility of severe anaphylactoid reactions, the risk of dosing errors,^{56,58,98} and the possibility of incomplete or delayed treatment because of anaphylactoid reactions.^{63,108}

IV NAC is dosed using a complex three-bag preparation system (see Dosing and Administration below) that has led to an up to 33% error rate including 19% of patients having a greater than 1 hour interruption of NAC.⁵⁶ Attempts at simplifying this system are described but have not been adequately studied for general use^{67,136} (Table A3–1).

TABLE A3–1. Three-Bag Method Dosage Guide ¹ for Patients Weighing ≥ 40 kg ^a				
Body Weight		Loading Dose (150 mg/kg in 200 mL D ₂ W over 60 minutes)	Second Dose (50 mg/kg in 500 mL D ₂ W over 4 hours)	Third Dose (100 mg/kg in 1000 mL D ₂ W over 16 hours)
(kg)	(lb)	Acetadote (mL) ^b	Acetadote (mL) ^b	Acetadote (mL) ^b
100	220	75	25	50
90	198	67.5	22.5	45
80	176	60	20	40
70	154	52.5	17.5	35
60	132	45	15	30
50	110	37.5	12.5	25
40	88	30	10	20

^aThe total volume administered should be adjusted for patients weighing less than 40 kg and for those requiring fluid restriction. ^bAcetadote is available in 30 mL (200-mg/mL) single-dose glass vials. D₂W = 5% dextrose in water.

Additional safety concerns have involved dosing for both small children and obese adults. The IV NAC dosing regimen

includes a milligrams per kilogram dose in a fixed water volume, leading to variability of IV NAC concentration.^{27,63} This leads to a large solute-free water administration in children, with the potential for hyponatremic seizures.¹⁴⁹ The NAC high concentration in obese adults potentially risks an increased rate of anaphylactoid reactions. Thus, alternative dosing strategies have been developed for children (constant 3% concentration)²⁷ and obese adults (ceiling weight of 100 kg; see Dosing).⁴²

The main disadvantage of the NAC PO formulation is the high rate of vomiting and the concern that vomiting may delay therapy.¹¹⁴ Delays in administration of NAC are correlated with an increased risk of hepatotoxicity.¹⁴¹ The IV route avoids an increased rate of vomiting in patients who typically are already nauseated and avoids the use of high-dose antiemetics that may alter mental status.⁹⁴ A potential disadvantage of PO NAC is that its absorption may be delayed up to one hour compared with IV NAC.⁶¹ Finally, PO NAC doses may be difficult to administer to patients with altered mental status because of aspiration risks; IV NAC offers a distinct advantage in these instances.

One theoretical, albeit unproven, advantage of PO NAC early in the course of toxicity is that direct delivery via the portal circulation yields a higher concentration of NAC in the target compartment of toxicity, the liver. Because of this first-pass clearance, PO NAC results in circulating NAC 20 to 30 fold lower than after IV dosing, suggesting that most PO NAC is taken up by the liver.^{24,61} However, an elevated serum NAC concentration may be an advantage of IV NAC administration when the liver is not the only target organ of NAC, such as liver failure accompanied by cerebral edema or in pregnancy.

Several economic analyses have concluded that IV NAC is less expensive than PO NAC,^{92,93} whereas others have concluded the opposite.⁷⁹ However, the majority of cost is associated with length of hospital stay and since none of these studies have taken into account that many patients treated with PO NAC now receive shorter courses than 72 hours,^{19,34} the studies do not represent current use.

Prior to the availability of the current IV formulation in the United States, the PO formulation was used intravenously with an excellent safety profile^{41,68,175} and without published evidence of infectious or febrile consequences.^{41,68} The IV use for this purpose is not generally recommended, but was historically effective and necessary in cases in which only the PO formulation was available and the patient had intractable vomiting or APAP induced fulminant hepatic failure.⁷⁹

Specific Indications for IV NAC. In addition to decisions based on cost, duration, safety, and ease of use, three situations exist for which the available information suggests IV NAC is preferable to PO NAC: (1) fulminant hepatic failure, (2) inability to tolerate PO NAC, and (3) APAP poisoning in pregnancy. Each of these requires further study for validation, but all three seem well supported by current information.

Fulminant hepatic failure is an important indication for IV NAC. IV is the only route that has been studied in liver failure.⁷¹ Although PO NAC may be effective, it has not been formally studied. Second, evidence that (some or all of) the benefit of NAC in liver failure is extrahepatic suggests that IV NAC is preferable.⁵⁶ IV NAC results in higher serum NAC concentrations, which presumably leads to more NAC delivery to critical organs. Finally, concomitant gastrointestinal bleeding, use of lactulose, and other factors make IV NAC more practical.

Common indications for IV NAC are for patients with very high APAP concentrations who are approaching or are more than 6 to 8 hours from the time of ingestion as well as those who are unable to tolerate PO NAC following a brief aggressive trial of antiemetic therapy. Use of IV NAC is logical to prevent further delays and resultant loss of NAC efficacy, even without proof that continued vomiting significantly limits NAC absorption.

The most controversial indication for IV NAC use is during pregnancy. Administration of IV NAC to the mother has the theoretical advantage of increased delivery to the fetus over PO NAC use. IV administration circumvents first-pass metabolism, presumably exposing the fetal circulation to higher maternal serum concentrations. Some studies have suggested that placental transfer of NAC to the fetus is limited.^{66,133} However, one case series found that the NAC concentration in cord or neonatal blood after PO maternal NAC administration equaled the NAC concentration that is achieved in patients treated with PO NAC.⁶⁴ Of course, an equivalent serum NAC concentration does not prove adequacy of therapy. Unlike the neonates studied, patients treated with PO NAC have extensive first-pass hepatic uptake before NAC entry into the serum, where NAC concentration was measured.^{24,61} Whether serum NAC concentration in the neonates studied reflects any significant hepatic NAC delivery is uncertain.

ROLE IN ACETAMINOPHEN TOXICITY

In acute overdose, treatment with NAC should be initiated if the serum APAP concentration is plotted on or above the treatment line on the Rumack-Matthew nomogram or the patient's history suggests an acute APAP ingestion of 150 mg/kg or greater and the results of blood tests will not be available within 8 hours of ingestion. In patients with chronic APAP ingestions, treatment with NAC should be initiated if either aspartate aminotransferase (AST) is above normal or the APAP concentration is above 10 µg/mL ([Chap. 35](#)).

IV NAC is approved by the FDA for treatment of potentially hepatotoxic quantity of APAP within 8 to 10 hours

following ingestion. The oral formulation is approved for use in a 72 hour protocol for APAP toxicity.

ROLE IN NONACETAMINOPHEN POISONING

Diverse investigations of NAC as a treatment for a number of xenobiotics associated with free radical or reactive metabolite toxicity are reported. Some of these xenobiotics include acrylonitrile, amatoxins, cadmium, chloroform, carbon tetrachloride, cyclophosphamide, 1,2-dichloropropane, doxorubicin, eugenol, pulegone, ricin, and zidovudine.^{31,44,47,154,155,157,162} NAC has not been studied well enough for any of these xenobiotics in humans to definitively recommend it as a therapeutic intervention. However, the best evidence supports the use of NAC in cases of acute exposures to cyclopeptide-containing mushrooms and carbon tetrachloride.^{31,47,162} NAC has also decreased cisplatin-induced nephrotoxicity in both rats and human cell cultures, although in vivo human data are sparse.^{7,122} NAC may be considered in cases of acute pennyroyal oil (ie, pulegone) or clove oil (eg, eugenol) ingestions based on their similarities to APAP-induced hepatotoxicity. Both pulegone and eugenol are converted to reactive metabolites that deplete glutathione, leading to centrilobular hepatic necrosis.^{153–156} NAC may be effective in treating patients with hepatotoxicity from chronic valproate use, given the evidence that the 2,4-diene valproic acid metabolite acts as an electrophile and reduces hepatic glutathione. However, there is no evidence that NAC is effective in treating patients with acute valproate toxicity and no evidence or theoretical efficacy in treating valproate-induced hyperammonemia. In animal studies NAC increases the excretion of several metals and other elements, including boron, cadmium, chromium, cobalt, gold, and methylmercury.^{13,15,31,59} The clinical usefulness of this effect remains unclear.

NAC has been studied as an oncological chemopreventive and antineoplastic^{3,36,84,123} as well as for lung injury,^{36,37} cardiac injury,^{143,144} multiorgan failure from trauma and sepsis,^{52,115,131,145} traumatic brain injury,^{14,153,174} chronic obstructive pulmonary disease,¹⁴⁸ ifosfamide-induced nephrotoxicity,⁵³ postcardiac surgery,⁸⁷ hepatorenal syndrome,⁶² H. pylori infections,⁸⁸ necrotizing enterocolitis,¹⁵¹ sickle cell disease,¹⁰² and bipolar disorder.¹⁸ NAC has extracellular antimutagenic effects, enhances repair of nuclear DNA damaged by carcinogens, and inhibits malignant cell invasion and metastases.^{36,104,116} Rescue NAC therapy has been studied with high-dose APAP (> 20 g/m²) used as chemotherapy in patients with select advanced malignancies.^{74,169}

NAC has been extensively studied to determine its effects on IV contrast-induced nephropathy. Pretreatment with either PO^{5,21,25,39,50,70,138,152} or IV^{12,43,91} formulations has been studied before angiography with mixed results. Absolute creatinine change in the positive studies remains quite small and is typically below 0.2 mg/dL.^{51,76} Recent large randomized trials found no reduction in the risk of nephrotoxicity after intravascular angiographic procedures² or in emergency department computed tomography,¹⁵⁹ and current knowledge suggests that NAC is ineffective for these indications.^{51,58,76,103,128}

NAC has been studied in the treatment of patients with non APAP-related acute liver failure with mixed results. In a randomized trial in adults, NAC improved transplant-free survival in early non-APAP-related acute liver failure (eg, mild encephalopathy), but had no effect in those with severe encephalopathy.⁸¹ However, although a study using historic controls suggests that NAC improves survival in children with non-APAP-related acute liver failure,⁷⁵ a randomized study showed no difference in 1 year survival rates and a lower 1 year transplant-free survival rate, particularly in children younger than 2 years of age.¹⁴⁷

NAC has been used for decades in cases of cyclopeptide-containing mushroom poisoning, particularly poisoning with *Amanita phalloides*. NAC therapy for amatoxin poisoning is largely based on the similarity of toxicity of amatoxin to APAP, specifically delayed onset of centrilobular hepatic necrosis. Decreases in intracellular glutathione stores were identified in isolated rat hepatocytes that were exposed by amanita extracts,⁶⁹ leading to the reasonable conclusion that supplying the tissue with thiols may decrease toxicity. In retrospective studies, patients treated with NAC had lower mortality rates than those treated with supportive care;⁴⁶ however, in animal studies, NAC has little effect on hepatotoxicity.¹⁵⁸

ADVERSE EVENTS AND SAFETY ISSUES

Oral NAC may cause nausea, vomiting, flatus, diarrhea, gastroesophageal reflux, and dysgeusia; generalized urticaria occurs rarely. Generalized anaphylactoid reactions described following IV NAC dosing^{6,17,23,35,49,60,86,90,111,118,161,165} are not noted after PO therapy and may be related to rate, concentration, or high serum NAC concentrations.^{16,111}

While the IV route ensures delivery, rate-related anaphylactoid reactions occur in up to 18% of patients.⁷² Most reactions are mild (6%) or moderate (10%) such as cutaneous reactions, nausea, and vomiting; severe reactions such as bronchospasm, hypotension, and angioedema are rare (1%).¹ Anaphylactoid reactions are more common in patients with lower [APAP] (25% if APAP < 150 µg/mL) than in those with high [APAP] (3% if APAP > 300 µg/mL),¹⁶⁶ because APAP decreases histamine release from mononucleocytes and mast cells in a dose-dependent manner.³²

If hypotension, dyspnea, wheezing, flushing, or erythema occurs, then NAC should be stopped and standard symptomatic therapy instituted. After the reaction resolves, NAC can be carefully restarted at a slower rate after one hour, assuming NAC is still indicated. If the reaction persists or worsens, IV NAC should be discontinued and a switch to PO NAC should be considered. Adverse reactions, confined to flushing and erythema, are usually transient, and NAC can be continued with meticulous monitoring for systemic symptoms that indicate the need to stop the NAC. Urticaria can be managed with diphenhydramine with the same precautions.¹¹ Iatrogenic overdoses with IV NAC have resulted in severe reactions, hypotension, cerebral edema, seizures, and death.^{1,11,58,90}

IV NAC decreases clotting factors and increases the prothrombin time in healthy volunteers and overdose patients without evidence of hepatic damage.^{65,85,99,107,167} This effect occurs within the first hour, stabilizes after 16 hours of continuous IV NAC, and rapidly returns to normal when the infusion is stopped.⁶⁵ International normalized ratio (INR) elevations are mild and are typically below 1.5 to 2.0. Because the INR is used as a marker of the severity of toxicity and is one of the criteria for transplantation, this adverse effect of NAC should always be considered when evaluating the patient's condition. An elevated INR that remains below 2 without other indicators of hepatic damage is probably related to the NAC.

SAFETY IN PREGNANCY AND NEONATES

Untreated APAP toxicity is a far greater threat to fetuses than is NAC treatment.^{33,119} NAC traverses the human placenta and produces cord blood concentrations comparable to maternal blood concentrations.⁶⁴ For treatment of the pregnant patient with APAP toxicity, IV NAC (not PO NAC) has the advantage of assuring fetal delivery of NAC due to reduction of the first pass metabolism. NAC is FDA Pregnancy Category B.

Limited data exist with regard to the management of neonatal APAP toxicity,^{9,80,121,134} although IV and PO NAC have been used safely.^{1,9} No adverse events were observed when preterm newborns were treated with IV NAC^{1,4,109} (Chaps. 31 and 35). The elimination half-life of NAC in preterm neonates was 11 hours compared with 5.6 hours in adults.⁴ When treating neonates, IV administration has the advantage of assuring adequate antidotal delivery and has been administered without adverse effects.^{4,109}

DOSING AND ADMINISTRATION

The standard IV NAC protocol is a loading dose of 150 mg/kg up to a maximum of 15 g in 200 mL of 5% dextrose in water (D₅W) (for adults) infused over 60 minutes followed by a first maintenance dose of 50 mg/kg up to a maximum of 5 g in 500 mL D₅W (for adults) infused over 4 hours followed by a second maintenance dose of 100 mg/kg up to a maximum of 10 g in 1000 mL D₅W (for adults) infused over 16 hours (6.25 mg/kg/h).

When NAC is administered orally, the patient should receive a 140-mg/kg loading dose either orally or by enteral tube. Starting 4 hours after the loading dose, 70 mg/kg should be given every 4 hours, for an additional 17 doses, for a total dose of 1330 mg/kg. The solution should be diluted to 5% and can be mixed with a soft drink to enhance palatability. If any dose is vomited within one hour of administration, then the dose should be repeated⁸³ or IV delivery used. Antiemetics (eg, metoclopramide, or ondansetron) should be used to ensure absorption.

Several other regimens, including 48 hours IV, 36 hours IV, 36 hours PO, and 20 hours PO protocols, are described; however, none of these has been adequately studied for general use^{34,140,170,176} (Chap. 35).

Conceptually, NAC therapy should be started if the patient is at risk of toxicity, continued as long as is necessary, and it should be stopped when the patient is no longer at risk of toxicity.¹⁷¹ For a detailed description of the indications for treating APAP toxicity with NAC, see Chap. 35. Briefly, in acute overdoses (from 4–24 hours after ingestion), NAC therapy should be initiated if the initial APAP concentration falls above the treatment line of the Rumack-Matthew nomogram. In acute overdoses where the patient arrives more than 24 hours following ingestion, then NAC should be started if the APAP concentration is detectable or if the AST is elevated. In repeated supratherapeutic ingestions, NAC therapy should be initiated if either the APAP concentration is detectable or the AST is elevated. For other scenarios, see Chap. 35.

Once the protocol is initiated, an APAP concentration and AST are evaluated prior to the end of the NAC infusion (20 hours for IV NAC) or at 24 hours (for oral NAC). If the APAP concentration is undetectable and the AST is normal, then NAC can safely be discontinued. NAC should be continued beyond the “protocol length” if the APAP concentration remains detectable or the AST is significantly elevated. There are no data to support what degree of AST elevation should be used as a cutoff for treatment. The NAC protocol should be continued until the APAP concentration is undetectable, there is no evidence of hepatic failure, and the AST, if it were elevated, is decreasing. If hepatic failure intervenes, then IV NAC should be administered at the dose of the “third bag” (16 hour infusion of 6.25 mg/kg/h) and continued until the patient has a normal mental status (or recovery from hepatic encephalopathy)⁵⁵ and the patient's INR decreases below 2.0¹¹⁹ or

until the patient receives a liver transplant.^{26,54,71}

For the rare patient who ingests exceptionally large doses of APAP, or who has prolonged and significantly elevated APAP concentrations, consideration should be given to treating with greater amounts of NAC once prolonged, massive APAP concentrations are evident.^{40,133,143} The rationale for increasing NAC dosing include that the IV infusion rate (6.25 mg/kg/h) was derived to treat a 16 g ingestion of APAP.¹²⁴ While it is effective for most patients who ingest APAP, an ingestion that is several times larger than 16 g may require additional NAC. In addition, published cases of patients who have developed hepatotoxicity despite early NAC therapy have ingested more than 16 g of APAP and been treated with the IV (6.25 mg/kg/h) infusion.^{40,132,142} There are no reported early NAC failures with the PO protocol.

No data exist to determine which, if any, alternative NAC dosing strategy is effective; however, it seems reasonable to increase NAC dosing if the hepatic exposure to APAP (and therefore NAPQI) is prolonged and massive. Several strategies have been theorized, but none have been studied. Potential strategies include:

1. Using the oral protocol for high-risk patients who can tolerate oral NAC
2. Administer both oral NAC and IV NAC simultaneously, an approach that increases initial loading and total doses
3. Base the IV NAC dosing on the ingestion size or [APAP]:¹²¹
 - a. If the ingestion is between 16 and 32 g, or the initial [APAP] is between the “300 line” and the “500 line,” then consider using 12.5 mg/kg/h as the 16 hour infusion rate.
 - b. If the ingestion is between 32 and 48 g, or the initial [APAP] is above the “500 line,” then consider using 18.75 mg/kg/h as the 16 hour infusion rate.
 - c. If the ingestion is greater than 48 g, then consider using 25 mg/kg/h as the 16 hour infusion rate.

Your poison control center can help with the most current information (1-800-222-1222).

There are no specific dosing guidelines for patients who are obese. However, it may be reasonable to limit PO and IV NAC dosing using a maximum weight of 100 kg. This maximum limit is not based on experimental evidence; however, patients who are larger than 100 kg have an equivalent hepatic volume and similar ingestion amounts as patients who weight less than 100 kg. Although dosing with a maximum weight is logical, it has not yet been adequately studied in obese humans.

Previously dosing information for IV NAC was unavailable for patients weighing less than 40 kg, and problems with osmolarity, sodium concentrations, and fluid requirements became apparent when improper dilutions were used. The package insert now gives specific information for dosing in these patients (Table A3–2).

TABLE A3–2. Three-Bag Method Dosage Guide by Weight for Patients Weighing < 40 kg^a

Body Weight		Loading Dose (150 mg/kg over 60 minutes)		Second Dose (50 mg/kg over 4 hours)		Third Dose (100 mg/kg over 16 hours)	
(kg)	(lb)	Acetadote (mL)	D ₁ W (mL) ^b	Acetadote (mL) ^b	D ₁ W (mL)	Acetadote (mL) ^b	D ₁ W (mL)
30	66	22.5	100	7.5	250	15	500
25	55	18.75	100	6.25	250	12.5	500
20	44	15	60	5	140	10	280
15	33	11.25	45	3.75	105	7.5	210
10	22	7.5	30	2.5	70	5	140

^aAcetadote is hypersmolar (2600 mOsm/L) and is compatible with D₁W, one-half normal saline (0.45% sodium chloride injection), and water for injection. ^bAcetadote is available in 30 mL (200-mg/mL) single-dose glass vials. D₁W = 5% dextrose in water.

The IV dosing of NAC is complicated because three different preparations must be prepared with each based on weight. A retrospective study estimated that there was a 33% medication error rate in the preparation and delivery of IV NAC.⁵⁶ To limit these errors, Tables A3–1 and A3–2 from the package insert, which give the appropriate doses and dilutions for adults and patients weigh less than 40 kg.¹ In addition, the following web site has a dosage calculator: <http://acetadote.com/dosecalc.php>.

FORMULATION

NAC is available as a 20% concentration in 30 mL single-dose vials designed for dilution before IV administration and

should also be diluted before administration.

SUMMARY

- NAC is the primary antidote for APAP toxicity.
- Limited evidence also supports NAC use in cyclopeptide containing mushroom toxicity (eg, *Amanita phalloides*), carbon tetrachloride, and pulegone toxicity (pennyroyal oil).
- NAC should be started if there is significant risk of toxicity and stopped when the risk of toxicity is gone and any toxicity that had occurred is resolving.
- Oral and IV NAC have essentially equivalent efficacy.
- IV NAC has approximately an 18% risk of anaphylactoid reactions, most of which are mild, and oral NAC has a 20% risk of vomiting.
- Higher doses of NAC should be considered for cases of massive ingestion or cases in which a prolonged high concentration of APAP is present.

36 COLCHICINE, PODOPHYLLIN, AND THE VINCA ALKALOIDS

Joshua G. Schier

COLCHICINE

History

The origins of colchicine and its history in poisoning can be traced to Greek mythology. Medea was the evil daughter (and a known poisoner) of the king of Colchis, a country that lay east of the Black Sea in Asia Minor. After being betrayed by her husband Jason (of Jason and the Argonauts), she killed their children and her husband's lover. Medea is often used plants of the Liliaceae family to poison her victims, one of which is *Colchicum autumnale*.^{25,144,192} The use of colchicum for medicinal purposes is reported in Pedanius Dioscorides *De Materia Medica*, an ancient medical text, written in the 1st century A.D.^{25,144,192} and subsequently in the 6th century A.D. by Alexander of Trallis, who recommended it for arthritic conditions.^{25,40,181,192,176} However, colchicum fell out of favor, perhaps because of its pronounced gastrointestinal (GI) effects, until it was reintroduced for dropsy and various other nonrheumatic conditions in 1763.^{25,192} In the late 18th century, a colchicum containing product known as Eau Medicinale reportedly had strong antigout effects.¹⁹² Colchicine, the active alkaloidal component in colchicum, was isolated in 1820 and rapidly became popular as an antigout medication.^{144,192} Benjamin Franklin reportedly had gout and is credited with introducing colchicine in the United States.¹⁴⁴ Colchicine is still used in the treatment of gout and has been used in a multitude of other disorders, including amyloidosis, Behçet syndrome, familial Mediterranean fever, chronic pericarditis, arthritis, pulmonary fibrosis, vasculitis, biliary cirrhosis, microcrystalline arthritis, certain spondyloarthropathies, calcinosis, and scleroderma.^{12,25,133,137} Unfortunately, systematic data supporting the efficacy of colchicine therapy in many of these other diseases are lacking.

Colchicine is derived from two plants of the Liliaceae family, *C. autumnale* (autumn crocus, meadow saffron, wild saffron, naked lady, son-before-the-father) and *Gloriosa superba* (glory lily).¹⁹² Colchicine is not distributed evenly in the

autumn crocus with the highest concentrations found in the bulb and seeds (0.8%) followed by the corm or underground stem (0.6%) and the flowers (0.1%).^{144,169,181} Colchicine concentrations within the plant peak during the summer months.¹⁴⁴ The leaves of *C. autumnale* closely resemble those of the *Allium ursinum* or wild garlic and have been mistaken for them.^{44,45,110} The tubers of *G. superba* may be confused with *Ipomoea batatas* (sweet potatoes).¹⁹²

There is a dearth of epidemiologic data on colchicine poisoning. The American Association of Poison Control Centers records several hundred overall exposures annually (Chap. 136). Most of these exposures are in adults and are categorized as unintentional. Approximately 10% of the cases with a recorded outcome typically have evidence of moderate or major toxicity or resulted in death.⁴¹ Although a limited number of cases are due to intentional suicidal ingestions, recent work suggests that therapeutic colchicine administration contributes to adverse health effects and in some cases death among hospitalized patients (probably related to failure to adjust dosing for renal impairment).¹⁶⁵ At least 50 adverse events (23 of which were fatalities) are linked to the use of intravenous (IV) colchicine.⁴ The US Food and Drug Administration announced its intent to stop the marketing of unapproved injectable drug compounds containing colchicine in 2009.⁴ Although all approved IV formulations in the United States were subsequently withdrawn, it may in theory be obtainable from compounding pharmacies and from other countries. Serious questions remain about the safety of colchicine in light of its extremely narrow therapeutic index.

Pharmacology

Colchicine is a potent inhibitor of microtubule formation and function, and thereby interferes with cellular mitosis, intracellular transport mechanisms, and maintenance of cell structure and shape.^{137,192} The ubiquitous presence of microtubules in cells throughout the body presents a wide variety of targets for colchicine poisoning.^{137,192} Colchicine accumulates in leukocytes and has inhibitory effects on leukocyte adhesiveness, amoeboid motility, mobilization, lysosome degranulation, and chemotaxis.^{25,51,61,88,95,186–188} At doses used clinically, colchicine inhibits neutrophil and synovial cell release of chemotactic glycoproteins.^{195,218} Colchicine also inhibits microtubule polymerization, which disrupts inflammatory cell-mediated chemotaxis and phagocytosis.¹⁹⁹ It reduces expression of adhesion molecules on endothelial and white blood cells and affects polymorphonuclear cell cytokine production.^{10,26,161} Colchicine also acts as a competitive antagonist at GABA_A receptors in a human ex-vivo model.²⁴³

Pharmacokinetics and Toxicokinetics

Oral colchicine is rapidly absorbed in the jejunum and ileum and has a bioavailability generally between 25% and 50%.^{25,203} It is highly lipid soluble^{19,25,192} with a volume of distribution that ranges from 2.2 to 12 L/kg, which may increase to 21 L/kg in overdose.^{168,196,197,230} Colchicine binding to plasma proteins approaches 50%.^{25,137,160,192} Protein binding is principally to albumin, although some binding to α_1 -glycoprotein acid and other lipoproteins is reported.²⁰³ During the first several hours after acute overdose, colchicine is sequestered in white and red blood cells in concentrations five to 10 times higher than in serum.²⁰³ Peak serum concentrations after ingestion occur between 1 to 3 hours.¹³⁷ Toxic effects usually do not occur with concentrations less than 3 ng/mL.^{89,160,239}

Colchicine is primarily metabolized through the liver with up to 20% of the ingested dose excreted unchanged in the urine.²³⁰ Colchicine undergoes demethylation by CYP3A4.^{120,229} Detoxification mainly occurs through deacetylation, demethylation, biliary secretion, and excretion in the stool.^{201,203} Enterohepatic recirculation of colchicine occurs.^{3,192}

Serum elimination half-lives ranging from 9 to 108 minutes are reported.^{17,107,192,203,240} However, upon closer examination, these times probably more accurately reflect a rapid initial distribution phase. The drug undergoes a more delayed terminal elimination phase, which ranges from 1.7 to 30 hours, depending on the individual compartment model used to estimate elimination and the amount of colchicine absorbed.^{3,93,192,197,201,203,230} These values are on the same order as, and probably reflect the tubulin–colchicine complex disassociation time.¹⁷⁶ Individuals with stage 5 chronic kidney disease (CKD) and liver cirrhosis may have elimination half-lives that are prolonged up to tenfold.¹³⁷ Colchicine can remain in measurable tissue quantities for a long time, as evidenced by its detection in white blood cells after 10 days and in urine 7 to 10 days after exposure.^{88,192} Colchicine can cross the placenta and is secreted in breast milk, but it is not dialyzable.¹³⁷ Postmortem examination of colchicine-poisoned patients reveals high concentrations within the bone marrow, testicles, spleen, kidney, lung, brain, and heart.¹⁹⁶

Drug Interactions. Colchicine metabolism is susceptible to drug interactions. Because colchicine is metabolized through CYP3A4, serum concentrations are susceptible to xenobiotics that alter the function of this enzyme, such as erythromycin, clarithromycin, and grapefruit juice.^{53,80,99,137} In particular, coadministration of clarithromycin and colchicine, especially in patients with CKD, increases the risk of fatal interaction.^{5,119} P-glycoprotein (PGP) expels and clears colchicine; therefore, PGP inhibitors directly affect the amount of colchicine eliminated and hence, toxicity.¹⁷⁶ For example, cyclosporine increases colchicine toxicity.^{85,137,216,217} Coadministration of colchicine with statin or fibrate drugs, nephrotoxins such as

nonsteroidal antiinflammatory drugs and angiotensinogen-converting enzyme inhibitors, and fluindione (antivitamin K anticoagulant) can result in colchicine poisoning.²³³

Pathophysiology

Microtubules play a vital role in cellular mitosis and demonstrates significant dynamic instability.^{22,87,127,210} Microtubules are made up of tubulin protein subunits, of which three are known to exist: α , β , and γ .^{127,154,210} These structures are highly dynamic with α - β -tubulin heterodimers, constantly being added at one end and removed at the other.^{127,128} Microtubules undergo two forms of dynamic behavior: dynamic instability, in which microtubule ends switch between growth and shortening phases, and tread milling, in which there is a net growth (addition of heterodimers) at one end and a shortening (loss) at the other.³⁰ Assembly and polymerization dynamics are regulated by additional proteins known as stabilizing microtubule-associated proteins (MAPs) and destabilizing MAPs.³⁰ These dynamic behaviors and a resultant equilibrium are needed for multiple cell functions, including cell support, transport, and mitotic spindle formation for cell replication.¹²⁷ Xenobiotics that bind to specific regions on tubulin can interfere with microtubule structure and function, thereby causing mitotic dysfunction and arrest.^{154,210} This leads to cellular dysfunction and death.²¹⁰ Xenobiotics that target microtubules can be generally divided into two categories: polymerization inhibitors (ie, vinca alkaloids, colchicine) and polymerization promoters (ie, taxanes, laulimalides).³⁰

Colchicine binds to a tubulin dimer at a specific region known as the colchicine-binding domain, which is located at the interphase of the α and β subunits of the tubulin heterodimer.^{30,111,127,182,210,234} This binding is relatively slow, temperature dependent, and generally irreversible, resulting in an alteration of the secondary structure of the protein.^{111,127,143,182,204} Colchicine binds at a second reversible but lower-affinity site on tubulin.^{127,143} The colchicine-tubulin complex binds to the microtubule ends and prevents further growth by sterically blocking further addition of dimers.³⁰ Conformational changes in the tubulin and colchicine complex also result as colchicine concentrations increase, which weakens the lateral bonds at the microtubule end.^{30,154,196,210} Lateral and longitudinal interactions between dimers within a microtubule help stabilize the structure. The number of tubulin-colchicine dimers incorporated into the microtubule determines the stability of the microtubule ends.³⁰ All of these processes may prevent adequate binding of the next tubulin subunit and result in cessation of microtubule growth.^{154,210} At low concentrations, colchicine arrests microtubule growth, whereas at high concentrations, colchicine can actually cause microtubule depolymerization through disassociation of tubulin dimers.³⁰

These conformational changes ultimately result in disassembly of the microtubule spindle in metaphase of cellular mitosis, cellular dysfunction, and death.^{91,111,127,182,204,210} Colchicine also inhibits microtubule-mediated intracellular granule transport.^{25,137} Some in vitro animal studies also show that colchicine might inhibit DNA synthesis by changing cell regulatory events at a critical time during the mitotic cycle.^{86,92,113,140}

Toxic Dose

The toxic dose for colchicine is not well established. An early case series suggested that patients who ingested greater than 0.8 mg/kg uniformly died and those who ingested above 0.5 mg/kg but less than 0.8 mg/kg would survive if given supportive care.³³ This information was based on a limited series of patients and is not generalizable.¹⁶⁶ More recent literature suggests that severe toxicity and even death may occur with doses smaller than 0.5 mg/kg, and patients can survive ingestions reported to be in excess of 0.8 mg/kg.^{16,81,100,163,166,220} This inability to accurately quantify the toxic dose in humans is likely due in great part to difficulty in dose estimation from the patient's history and significant advances in supportive care. Furthermore, many comorbid conditions (eg, CKD, liver disease) and other pharmaceuticals, which, when coadministered, can enhance the adverse effects of colchicine, complicating the determination of a minimal toxic dose.

Clinical Presentation

The clinical findings in patients poisoned with colchicine are commonly described as triphasic (Table 36–1).^{115,150,168,220} GI irritant effects, such as nausea, vomiting, abdominal distress, and diarrhea, occurring within several hours of an overdose^{8,43,45,71,79,129,150,155,236} and may lead to severe volume depletion.^{99,118,146,166,168,170,220,242} This first stage usually persists for the first 12 to 24 hours following ingestion.^{118,150} The second stage is characterized by widespread organ system dysfunction, particularly the bone marrow, and lasts for several days.^{45,81,166,168,220} The final phase is characterized by recovery or death, and the progression can usually be defined within one week.^{115,118,150,220}

TABLE 36–1. Colchicine Poisoning: Common Clinical Findings, Timing of Onset, and Treatment

Phase	Time ^a	Signs and Symptoms	Therapy/Follow-Up
I	0–24 hours	Nausea, vomiting, diarrhea Salt and water depletion Leukocytosis	Antiemetics Consider GI decontamination IV fluids Close observation for leukopenia
II	1–7 days	Risk of sudden cardiac death (24–48 hours) Pancytopenia Acute kidney injury Sepsis Acute respiratory distress syndrome Electrolyte imbalances Rhabdomyolysis	ICU admission and appropriate resuscitation G-CSF Hemodialysis Antibiotics Oxygen, mechanical ventilation Repletion as needed IV fluids, hemodialysis
III	> 7 days	Alopecia (may not develop for 2–3 weeks) Myopathy, neuropathy, or myoneuropathy	Follow-up within 1–2 months EMG testing, biopsy and neurologic follow-up as needed

^aThe interval time course is not absolute, and overlap of symptom presentation may occur.

EMG = electromyography; G-CSF = granulocyte-colony stimulating factor; GI = gastrointestinal; ICU = intensive care unit; IV = intravenous.

After overdose, the hematopoietic effects of colchicine are characterized by an initial leukocytosis, which may be as high as 30,000/mm³. This is followed by a profound leukopenia, which may be lower than 1000/mm³ and is commonly accompanied by pancytopenia, usually beginning 48 to 72 hours after overdose.^{25,43,93,99,114,150,172} The hematopoietic manifestations occur as a result of the effects of colchicine on bone marrow cell division.^{40,118,153,196,242} A rebound leukocytosis and recovery of all cell lines occur if the patient survives.

Colchicine toxicity is associated with the development of dysrhythmias and cardiac arrest.^{40,115,118,150,168} Sudden cardiovascular collapse from colchicine typically occurs between 24 to 36 hours after ingestion.^{40,52,150,153,166} Profound hypovolemia and shock may contribute to this collapse,^{25,99,166,168,220} but colchicine also has direct toxic effects on skeletal and cardiac muscle.^{36,62,148,156,167,237,242}

Myopathy,^{46,47,209,247} neuropathy,^{13,140} and combined myoneuropathy^{11,64,72,84,135,136,193,215,253} result from both long-term therapy and acute poisoning.¹⁴⁰ Combined myoneuropathy is reported more often, with myopathy dominating the clinical picture.^{11,64,72,135,136,193,215,253} Myoneuropathy is often initially misdiagnosed as polymyositis or uremic neuropathy (caused by coexistent kidney failure).^{13,136} Myoneuropathy usually develops in the context of chronic, therapeutic dosing in patients with some baseline CKD,^{11,64,72,84,134,136,193,215,253} although it may also occur in the presence of normal kidney function.¹⁹⁰ Patients may present with proximal limb weakness, distal sensory abnormalities, distal areflexia, and nerve conduction problems consistent with an axonal neuropathy.^{136,185} A small amount of myelin degeneration is reported on autopsy, which suggests a myelinopathic component.⁴² The myopathy is characterized by vacuolar changes on biopsy and accompanied by lysosome accumulation.^{11,84,136,253} An elevated serum creatine kinase concentration is present concurrently with symptoms.^{136,168} Weakness usually resolves within several weeks of drug discontinuation.¹³⁶ Myopathy may also occur when hydroxymethylglutaryl-coenzyme A reductase inhibitors are concomitantly used in patients with renal insufficiency.⁶ Myopathy symptoms typically resolve within 4 to 6 weeks, although it may take up to 6 to 8 months in some patients.²⁴⁷

Acute respiratory distress syndrome occurs with colchicine toxicity.^{18,71,114,158,208,211} The etiology is not well understood but may result from several factors, including respiratory muscle weakness, multisystem organ failure, and possibly direct pulmonary toxicity.^{71,150,158,208,228} Other indirect effects of colchicine include acute kidney injury (AKI) and various electrolyte abnormalities resulting from fluid loss and impaired glomerular filtration rate.^{25,81,99,140,168}

Alopecia, which is usually reversible, is a well-described complication that occurs 2 to 3 weeks after poisoning.^{12,25,93,99,100,118,143,227} Dermatologic complications range in severity from epithelial cell atypia to toxic epidermal necrolysis.^{9,15,91,98,200} Neurologic effects, including delirium, stupor, coma, and seizures, might be at least partly

attributable to the multisystem disease caused by poisoning and not necessarily a direct effect of colchicine.^{46,172,192,211} The cause of seizures is unclear but it might be partly attributable to antagonism of GABA_A receptors.²⁴³ Other reported complications of colchicine poisoning include bilateral adrenal hemorrhage,^{66,224} disseminated intravascular coagulation,^{118,192,211} pancreatitis,^{172,232} and liver dysfunction.^{46,168,192}

Although uncommon, poisoning from IV colchicine administration has occurred. Clinical and laboratory manifestations are similar to those that occur after oral exposure including multisystem organ dysfunction and cytopenias.⁵⁵

Colchicine does not appear to be a significant human teratogen but the limited work on this subject is not definitive.⁷⁶

Diagnostic Testing

Colchicine concentrations in body fluids are not available in a clinically relevant time frame and have no well-established correlation with severity of illness. However, effective steady-state serum concentrations for treatment of patients with various illnesses are reported as 0.5 to 3.0 µg/L.¹⁶⁰ Concentrations > 3.0 µg/L can be associated with toxicity depending on the clinical situation and concentrations > 24 µg/L are definitely associated with toxicity.^{89,160,239,249} Serum concentrations do not correlate well with ingested dose in massive oral overdose settings.⁷⁵ Initial laboratory monitoring should include a complete blood count (CBC), serum electrolytes, renal and liver function tests, creatine kinase, phosphate, calcium, and magnesium. A prothrombin time, activated partial thromboplastin time, urinalysis, and other focused testing can be considered depending on clinical suspicion for different end-organ injury. The need for other laboratory studies, such as a troponin, arterial or venous blood gas, lactate, fibrinogen, and fibrin split products, should be considered, depending on the clinical situation. Following significant overdose or in any case if cardiac toxicity is present or suspected, serial troponins (every 6–12 hours) should be performed because increasing concentrations may be predictive of cardiovascular collapse.^{96,237} Electrocardiography and chest radiography should also be obtained. Serial CBCs are indicated (at least every 12 hours) to evaluate for the development of depression in cell lines. Bile appears to be the biologic matrix of choice for postmortem testing, probably due to normal postmortem biologic processes that can increase blood colchicine concentration.^{28,171} One colchicine-associated fatality who had a premortem blood colchicine concentration of 50 µg/L, also had a postmortem femoral blood concentration of 137 µg/L and a bile concentration above 600 µg/L.²⁴⁹ Another reported a postmortem blood concentration of 60 µg/L.² Two IV colchicine-associated fatalities had postmortem blood colchicine concentrations of 32 µg/L and 44 µg/L.⁵⁵

Management

Treatment for patients with colchicine toxicity is mainly supportive, which includes IV fluid replacement, vasopressor use, hemodialysis (as indicated for acute kidney injury), antibiotics for suspected secondary infection, colony-stimulating factors, and adjunctive respiratory therapy (endotracheal intubation, positive end-expiratory pressure), as necessary. Consultation with nephrologists and hematologists may be useful. In severe poisoning, intraaortic balloon pump therapy and extracorporeal membrane oxygenation therapy may be of help but there is no proof of clinical benefit.¹⁷⁹

Because most patients with an acute oral colchicine overdose present several hours after their ingestion, vomiting has already begun, and the utility of GI decontamination is inadequately defined. However, given the extensive morbidity and mortality associated with colchicine overdose, orogastric lavage should be considered in patients who present within 1 to 2 hours of ingestion and are not already vomiting.^{1,35,235} A dose of activated charcoal (AC) should be administered after lavage, or in its place if lavage is not appropriate or possible in the judgment of the physician. Since limited evidence suggests that colchicine undergoes some enterohepatic recirculation, administration of a single dose of AC to a patient presenting to a health care facility beyond 2 hours following ingestion can be considered if no contraindications exist. Multiple-dose AC (MDAC) can also be considered in these patients for the same reason.^{3,192} The delay in presentation to a health care facility coupled with the fact that patients often have GI symptoms such as vomiting limits the potential benefit of using MDAC. However, antiemetic medications can be given to control emesis and facilitate AC administration (Antidotes in Depth: A1).

Experimentally, colchicine-specific antibodies can restore colchicine-affected tubulin activity in vitro and were successfully used in a single case of severe colchicine poisoning.²¹ The administration of Fab fragments was temporally associated with a dramatic improvement in clinical and hemodynamic status. This improvement was also associated with a significant increase in serum colchicine concentrations, which suggests a redistribution of drug into the intravascular space.²¹ Unfortunately, this therapy is not commercially available.

Granulocyte-colony stimulating factor (G-CSF) is useful in the treatment of patients with colchicine-induced leukopenia and thrombocytopenia.^{69,109,131,252} The dose of G-CSF, the dosing frequency, and the route of administration were variable in the reported cases.^{69,109,131,252} G-CSF should be started if the patient develops leukopenia. Dosing should be in accordance with the manufacturer's instructions.

Hemodialysis and hemoperfusion are not viable options to enhance colchicine clearance based on its large volume of

distribution, but hemodialysis may be required if AKI is severe.^{24,31,32,196,197,230,242} Whole blood and plasma exchange have been suggested for cases presenting with lethal-dose colchicine exposures, but evidence of efficacy is lacking, and therefore these procedures are not recommended at this time.¹⁷⁹

Because of the significant morbidity and mortality associated with colchicine toxicity, all symptomatic patients with suspected or known overdoses should be admitted to the hospital for observation. Because these patients have a risk of sudden cardiovascular collapse within the first 24 to 48 hours¹⁶⁶ intensive care unit monitoring is recommended for at least this initial time period. Troponin should be checked every 6 to 12 hours during this period because increasing results may suggest an increased risk of cardiotoxicity and cardiovascular collapse.^{96,237} CBCs should be followed at least daily to evaluate for cytopenias. Poisoned patients manifest GI signs and symptoms within several hours of ingestion and should be observed for at least 8 to 12 hours. Patients who do not manifest GI signs and symptoms within that time period after ingestion are unlikely to be significantly poisoned.

PODOPHYLLUM RESIN OR PODOPHYLLIN

History

Podophyllin is the name often used to refer to a resin extract from the rhizomes and roots of certain plants of the genus *Podophyllum*.^{74,103} Examples include the North American perennial *Podophyllum peltatum* (May apple or mandrake), the related Indian species *Podophyllum emodi*, and the Taiwanese *Podophyllum pleianthum*.⁷⁴ It is more descriptive to refer to it as podophyllum resin.^{74,103} Podophyllum resin, or podophyllin, contains at least 16 active compounds.^{57,74,103} These include a variety of lignins and flavonols, including podophyllotoxin, picropodophyllin, α - and β -pellatins, desoxypodophyllotoxin, and quercetin.^{54,57,74,103} Podophyllotoxin, a component of podophyllin, is a potent microtubular poison, similar to colchicine, and causes similar effects in overdose.⁷⁴

The first reported modern era medicinal use of podophyllin preparations was as a laxative in the 19th century.^{54,57,188} Its cathartic properties, and its potential toxicity, were noted as early as 1890, when the first fatality from podophyllin was recorded.^{212,246} Podophyllin was used to treat individuals with a variety of other health issues, including liver disease, scrofula, syphilis, warts, and cancer.⁷⁴ Etoposide and teniposide are semisynthetic derivatives of podophyllotoxin used as chemotherapeutics.⁷⁴

Poisoning usually is caused by systemic absorption after topical application, after ingestion of the resin or plant, and after consumption of a commercial preparation of the extract. Systemic toxicity is described after unintentional dispensing of the incorrect herb, and after ingestion of herbal preparations containing podophyllin.^{58,59,78}

Pharmacology

Podophyllin is primarily used in modern pharmacopeia as a topical treatment for patients with verruca vulgaris and condyloma acuminatum.^{54,90,139} The active ingredient is believed to be podophyllotoxin.^{19,74,130,212,226,238,248} Podophyllotoxin exists in the plant as a β -D-glucoside.^{90,130,212} Numerous synthetic and semisynthetic derivatives of podophyllotoxin exist; however, the most important are probably the chemotherapeutics etoposide and teniposide.⁷⁴ The antitumor effect of etoposide and teniposide results from their interaction with topoisomerase II and free radical production, leading to DNA strand breakage, an effect not shared by podophyllin and colchicine.^{50,74} Etoposide and teniposide also arrest cell growth in the late S or early G2 phase of the cell cycle.^{50,74,97} Further discussion of these xenobiotics can be found in [Chap. 52](#).

Pharmacokinetics and Toxicokinetics

Very limited information exists regarding the pharmacokinetics of podophyllin as a preparation or for its major active ingredient, podophyllotoxin. Podophyllotoxin is highly lipid soluble and can easily cross cell membranes.^{90,101,175,212} It can be eliminated through the bile with a half-life of 48 hours.^{54,65} However, review of the referenced articles failed to adequately support this elimination half-life and may have been based solely on observed clinical course.⁶⁵

Absorption of podophyllotoxin was measured in seven men after application of various amounts of a 0.5% ethanol podophyllotoxin preparation for condylomata acuminata.²³⁸ Peak serum concentrations of 1 to 17 $\mu\text{g/L}$ were achieved within 1 to 2 hours after administration of doses ranging from 0.1 to 1.5 mL (0.5–7.5 mg).²³⁸ Patients treated with 0.05 mL or less had no detectable podophyllotoxin in their serum. Administration of 0.1 mL yielded peak serum concentrations up to 5 $\mu\text{g/L}$ within 1 to 2 hours and up to 3 $\mu\text{g/L}$ at 4 hours. Administration of 1.5 mL yielded peak serum concentrations ranging from 5 to 9 $\mu\text{g/L}$ within 1 to 2 hours; 5 to 7 $\mu\text{g/L}$ at 4 hours; 3 to 4.5 $\mu\text{g/L}$ at 8 hours; and 3.5 $\mu\text{g/L}$ at 12 hours.²³⁸

Pathophysiology

The components of podophyllin have numerous actions within the cell, including inhibition of purine synthesis, inhibition of purine incorporation into RNA, reduction of cytochrome oxidase and succinoxidase activity, and inhibition of microtubule structure and function.^{54,97,241} Podophyllotoxin causes toxicity similar to colchicine^{74,248} because of binding to tubulin subunits and interference with subsequent microtubule structure and function.^{74,248} Radiolabeled podophyllotoxin inhibits colchicine binding to tubulin, suggesting that their binding sites overlap.⁷⁴ Podophyllotoxin binds more rapidly than colchicine, and in contrast to colchicine, binding is reversible.⁷⁴ Podophyllotoxin also inhibits fast axoplasmic transport similar to colchicine by interference with microtubule structure and function.^{185,233} Many other compounds, such as the vinca alkaloids, cryptophycins, and halichondrins, also inhibit microtubule polymerization in a similar manner.¹²⁸

Toxic Dose

The minimum toxic dose associated with podophyllin ingestion is unknown. Limited information on the situations surrounding the few case reports of podophyllin poisoning that do exist does not provide sufficient detail from which to estimate it.

Clinical Presentation

Podophyllin poisoning is described after both ingestion,^{49,60,78,94,116,151,202,245} and absorption following cutaneous application.^{152,159,162,183,194,221,223} Toxicity also is reported following IV administration of podophyllotoxin¹⁰⁶ and ingestion of mandrake root or herbal remedies containing podophyllin.^{78,94,246} Nausea, vomiting, abdominal pain, and diarrhea usually begin within several hours after ingestion.^{65,101,106,116,152,157,159,194,202,212,221,245,246} Symptoms of poisoning might be delayed for 12 hours or more after cutaneous exposure to podophyllin and are often caused by improper usage (excessive cutaneous exposure, interruption in skin integrity, or failure to remove the preparation after a short time period).^{152,157,162,212} Initial clinical findings are not necessarily determined by the route of exposure.¹⁵²

Alterations in central and peripheral nervous system function tend to predominate in podophyllin toxicity. Some patients present with, or rapidly progress to, confusion, obtundation, and coma.^{49,65,78,151,157,159,162,194,202,221,223,226,245}

Delirium and both auditory and visual hallucinations occur during the initial presentation.^{67,90,223} Patients develop paresthesias, lose deep tendon reflexes, and might develop plantar extension.^{49,57,60,65,78,151,159,162,177,212,223,233} Cranial nerve involvement, including diplopia,⁵⁷ nystagmus,⁶⁵ dysmetria,⁶⁰ dysconjugate gaze,²²³ and facial nerve paralysis,⁶⁷ are all reported. Patients who recover from the initial event are at risk of developing a peripheral sensorimotor axonopathy.^{60,65,78,90,151,159,175,177,194,212,223} The reported duration for recovery from podophyllin-induced axonopathy is variable but can take several months.^{65,78,159,175} Dorsal radiculopathy¹⁰¹ and autonomic neuropathy are also reported.¹³⁹ There may be a mild myelopathic component in the neuropathy.⁵⁹

Hematologic toxicity from podophyllin most likely results from its antimitotic effects. A review of the limited literature suggests that it is similar to colchicine but is not nearly as consistent in its pattern, severity, and frequency. An initial leukocytosis^{159,162,194,212} may occur after poisoning, which can be followed by leukopenia, thrombocytopenia, or generalized pancytopenia.^{116,139,157,159,212,221} In patients who recover, cell lines tend to reach their nadir within 4 to 7 days after exposure.^{90,116,159,194,221}

Other complications of poisoning include fever,¹⁵⁷ ileus,^{90,157,223} elevated liver function tests,^{78,116,159,221,245} and hyperbilirubinemia,¹¹⁶ coagulopathy,¹¹⁶ seizures,^{67,202} and AKI.^{157,245} Teratogenic effects resulting from exposure during pregnancy may also occur.^{57,130}

Diagnostic Testing

Podophyllin or podophyllotoxin concentrations are not readily available. Routine testing for suspected or known podophyllin poisoning should include routine laboratory tests and other targeted testing, as needed. Serial CBCs should be obtained in cases of poisoning to evaluate for pancytopenia.

Management

Management primarily consists of supportive and symptomatic care. Orogastric lavage may be considered following recent ingestion based on its high toxicity profile.^{35,235} If the patient presents within the first several hours of ingestion, then a dose of AC should be given. Any cutaneously applied podophyllin should be removed and the area thoroughly cleansed. Supportive and symptomatic care should be instituted as needed. Patients either progress to multisystem organ dysfunction and death or recover. CBCs should be monitored similarly to colchicine poisoning (at least daily).

A few case reports of treatment with extracorporeal elimination techniques exist. These reports include resin

hemoperfusion¹¹² and charcoal hemoperfusion.^{159,212} The role these procedures played in the clinical courses is unclear. As a result, firm recommendations regarding the use of these techniques cannot be made at this time.

Patients with significant ingestions of podophyllin develop GI symptoms within a few hours,^{60,94,116,177,245,246} but patients may also present with primarily neurologic symptoms, such as confusion or obtundation.^{49,54,90,152} An isolated number of cases suggest the onset of toxicity can be delayed for as long as 12 hours.^{49,54,65,78} Cutaneous exposure might result in even further delayed toxicity because systemic absorption is delayed and symptom onset is more insidious.^{90,139,162,194,212,221,223} Patients probably should be observed for toxicity for at least 12 hours after ingestion and perhaps even longer after dermal exposures. Asymptomatic patients with unintentional exposures and good follow up that are discharged after 12 to 24 hours should have scheduled follow up with their primary care physician and a repeat CBC obtained within 24 hours.

VINCRIStINE AND VINBLASTINE

History

More than 150 different alkaloidal compounds can be isolated from the periwinkle plant (*Catharanthus roseus*), most of which have been used to manage illness from a variety of medical disorders including cancer, scurvy, diabetes, toothache, and hypertension.²⁵⁰ Among these 150 are about 20 different compounds that have antineoplastic activity. Vincristine and vinblastine are pharmaceuticals derived from compounds in the periwinkle plant and are probably among the most commonly used vinca alkaloid derivatives in medicine.¹⁹¹ They are typically used as part of a chemotherapy regimen for various cancers. Both are administered intravenously and should never be administered intrathecally. Intrathecal administration of vinblastine or vincristine is always the result of an error, is a neurosurgical emergency, and is associated with life-threatening complications⁷ (Special Considerations: SC3). There are a few case reports of intramuscular administration of these chemotherapeutics but they will not be discussed since there are so few and the reader is referred to the primary literature for further information.^{20,184} Although other vinca derivatives exist, and sharing similar modes of action (causing microtubule dysfunction); this section will focus primarily on vincristine and vinblastine. Regardless, the pathophysiology of disease, clinical manifestations of illness and management of poisoning from similar compounds and the plant itself is similar to vincristine and vinblastine.²⁵⁰

Pathophysiology

Vincristine and vinblastine are used specifically for the treatment of patients with leukemias, lymphomas, and certain solid tumors. Their mechanism of activity is similar to that of colchicine, podophyllotoxin, and the taxoids (eg, paclitaxel, docetaxel).^{73,180} These chemotherapeutics disrupt microtubule assembly from tubulin subunits by either preventing their formation or depolymerization, both of which are necessary for routine cell maintenance. Vinblastine binds to the β -subunit of the tubulin heterodimer at a specific region known as the vinblastine-binding site.¹⁸² Mitotic metaphase arrest is commonly observed because of the inability to form spindle fibers from the microtubules. Cell death quickly ensues because of the interruption of these homeostatic functions, accounting for the clinical manifestations.

The mechanism of neurotoxicity is not well understood but is probably related to inhibition of microtubular synthesis, which leads to axonal degeneration in the peripheral nervous system.^{102,178} Brain biopsy of a patient who experienced a vincristine-related death showed neurotubular dissociation, which is characteristic of vincristine damage in experimental animals.^{38,63}

Pharmacokinetics

After IV administration, vincristine is rapidly distributed to tissue stores and highly bound to proteins and red blood cells.⁴⁸ Plasma protein binding ranges from 50% to 80%.¹⁸⁹ In more than 50% of children given IV vincristine, serum concentrations were not detected 4 hours after administration.¹⁶⁴ Elimination of vincristine occurs via the hepatobiliary system,⁴⁸ and it has a terminal half-life of about 24 hours.¹⁷⁴ Patients with hepatic dysfunction are susceptible to toxicity. Vincristine overdose is the most frequently reported antineoplastic overdose in the literature. This is because there are at least four different potential inappropriate ways to dose and administer vincristine, including confusing it with vinblastine, misinterpreting the dose, administering it by the wrong route, and confusing two different-strength vials. The normal dose of vincristine is 0.06 mg/kg, and a single dose should not exceed 2 mg for either an adult or child.

Drug Interactions. Administration of itraconazole with therapeutic doses of intravenously administered vincristine can cause toxicity probably for two reasons: (1) itraconazole-induced inhibition of certain cytochrome P450 enzymes (most likely the CYP3A subfamily) delays vincristine metabolism in vivo, and (2) inhibition of PGP mediated efflux of vincristine from inside cells, where it then accumulates.¹⁴ Coadministration of other azole antifungals, cyclosporine, isoniazid, erythromycin, mitomycin C, phenytoin, and nifedipine are also implicated in vincristine toxicity for the same

aforementioned reasons.^{77,206,207}

Toxic Dose

The minimum toxic doses associated with adverse health effects from a single dose of vincristine and vinblastine are not well established. However, chemotherapeutic regimens tend to keep single doses at or below 2 mg to decrease the likelihood of peripheral neuropathy. Unfortunately, toxicity occurs with cumulative dosing over time, as which typically occurs with chemotherapeutic regimens. Peripheral neuropathy tends to begin after a cumulative dose (administered over multiple sessions, not all at once) of 30 to 40 mg.²⁹

Clinical Presentation

Despite their similarity in structure, vincristine and vinblastine differ in their clinical toxicity. Vincristine produces less bone marrow suppression and more neurotoxicity than does vinblastine. During the therapeutic use of vincristine, myelosuppression occurs in only 5% to 10% of patients.¹¹⁷ However, this effect is common in the overdose setting, and when it occurs, the need for blood products and concern for overwhelming infection is apparent.¹⁴² The decrease in cell counts begins within the first week and may last for up to 3 weeks. Other manifestations of acute vincristine toxicity are mucositis, central nervous system disorders, and syndrome of inappropriate antidiuretic hormone secretion (SIADH; Chap. 19).

Central nervous system disorders are varied and unusual during therapeutic vincristine therapy because of its poor penetrance of the blood–brain barrier. However, they are more common when there is delayed elimination, damage to the blood–brain barrier, overdose, or inadvertent intrathecal administration. Generalized seizures may occur from 1 to 7 days following exposure.^{121,126,132,222} Other manifestations are depression, agitation, insomnia, and hallucinations. Vincristine stimulation of the hypothalamus may be responsible for the fevers and SIADH noted in overdosed patients.¹⁹⁸ The fevers begin 24 hours after exposure and last 6 to 96 hours. Serum electrolytes must be monitored, typically for 10 days.

Autonomic dysfunction may occur, and it commonly includes ileus, constipation, and abdominal pain. Paraparesis, paraplegia, atony of the bladder, cranial nerve palsies (specifically ptosis), hypertension, and hypotension may also occur.^{77,83,132,254}

Ascending peripheral neuropathies can occur following inadvertent large ingestions and during routine chemotherapy. The risk can be limited somewhat by keeping the total for a single dose below 2 mg.²¹³ Neuropathy may appear after an overdose, starting at about 2 weeks and lasting for 6 to 7 weeks. Paresthesias, neuritic pain, ataxia, bone pain, wrist drop, foot drop, involvement of cranial nerves III to VII and X, and diminished reflexes may be observed.²⁴⁴ The incidence of paresthesia increases with dose and is reported to be 56% in patients treated at doses between 12.5 and 25 µg/kg.¹¹⁷ At a dose of 75 µg/kg, the incidence of patients with a sensory disorder increased by sixfold. The loss of reflexes, the earliest and most consistent sign of vincristine neuropathy, is maximal at 17 days after a single massive dose. Muscular weakness is a limiting point in therapy and typically involves the distal dorsiflexors of the extremities, although laryngeal involvement is also reported.^{138,205} These severe neurologic symptoms may be reversed by either withholding therapy or reducing dosage upon manifestation of these findings.¹³⁸ Unlike the vinca alkaloids, taxol-induced peripheral neuropathy is predominantly sensory and resolves faster with discontinuation.¹⁴¹ This is because of the different effects on microtubule assembly by these chemotherapeutics.

Vincristine-associated myocardial infarctions are reported, but their cause is not understood.^{147,214,225,251} They may be related to vinca alkaloid–induced platelet aggregation, coronary artery spasm, or increased sensitivity of myocardium to hypoxia.

Although rare, IV vincristine administration may be associated with an allergic-type cutaneous reaction.¹⁷³

Diagnostic Testing

Determination of vincristine and vinblastine concentrations is not readily available at most hospitals (Table 36–2). Routinely available laboratory tests such as electrolyte panels, kidney function tests, and others can be used as needed to assess the patient as indicated.

TABLE 36–2. Comparison of Antimitotic Overdose

	Colchicine	<i>Podophyllum Resin</i>	Vincristine	Vinblastine
Route of exposure	PO	PO and cutaneous	IV	IV
Initial symptoms	GI*	GI* and/or neurologic effects (obtundation, confusion, delirium)	GI effects,* fever, neurologic effects	GI effects,* fever, myalgias, neurologic effects
Initial symptom onset	Several hours after ingestion; delayed onset beyond 12 hours very unlikely	Several hours after ingestion; delayed presentation (past 12 hours) is possible, especially in those with a cutaneous route of exposure	Usually within 24–48 hours	Usually within 24–48 hours
Hematotoxic effects	Leukocytosis (24–48 hours after ingestion); pancytopenia (beginning 48–72 hours after ingestion)	Similar to colchicine; however, not well characterized and reported less frequently	Hematotoxicity may occur; less toxicity compared with vinblastine	Hematotoxicity may occur; more toxicity compared with vincristine
CNS effects	Late (48–72 hours after ingestion); obtundation, confusion, and lethargy secondary to progression of MSD	Can be early (< 12 hours after ingestion); CNS toxicity may occur later or secondary to progression of MSD	Variable; cranial neuropathies; seizures; obtundation, confusion, and lethargy may occur because of progression of MSD	Variable; cranial neuropathies; obtundation, confusion, and lethargy may occur because of progression of MSD
Delayed PNS effects	Myoneuropathy most common; reported most often in chronic colchicine users with renal insufficiency	Peripheral sensorimotor axonopathy	Autonomic and ascending peripheral neuropathy; increased severity compared with vinblastine	Can see autonomic and peripheral neuropathy; decreased severity compared with vincristine
Clinical course	Recovery or MSD and death	Recovery or MSD and death	Recovery or MSD and death; May develop SIADH	Recovery or MSD and death; may develop SIADH
Management	Supportive; GI decontamination; G-CSF for neutropenia	Supportive; consider GI decontamination for oral exposures and skin decontamination for cutaneous exposures	Primarily supportive; G-CSF for neutropenia For treatment of intrathecal overdoses see Special Considerations: SCI	Primarily supportive; G-CSF for neutropenia; consider exchange transfusion, plasmapheresis or plasma exchange For treatment of intrathecal overdoses see Special Considerations: SCI

*Nausea, vomiting, diarrhea, abdominal discomfort.

CNS = central nervous system; G-CSF = granulocyte colony-stimulating factor; GI = gastrointestinal; IV = intravenous; MSD = multisystem organ dysfunction; PNS = peripheral nervous system; PO = oral; SIADH = syndrome of inappropriate antidiuretic hormone secretion.

Management

Generalized seizures can be a life-threatening complication of vincristine or vinblastine overdose (Table 36–2). Treatment with benzodiazepines or phenobarbital is usually successful; phenytoin was used successfully in a patient with known barbiturate hypersensitivity.¹³² Prophylactic phenobarbital and benzodiazepines were used to prevent seizures in two patients.^{56,134} Dysrhythmias and alterations in blood pressure may also be expectantly managed. Calcium channel blockers (nifedipine and amlodipine) were used to control hypertension in a patient with vincristine overdose.⁵⁶ Blood counts must be monitored daily, and G-CSF may be used to treat neutropenia.^{56,142,222} However, the red blood cell response from the use of erythropoietin may be limited because of the induction of metaphase arrest in the erythroblasts.¹⁴⁹

The symptoms of acute toxicity usually last for 3 to 7 days, and the neurologic sequelae may last for months before some resolution is observed. Nerve conduction studies are helpful in assessing the extent of any clinical signs and symptoms of peripheral neuropathy.

Clinical findings of a peripheral neuropathy may appear following an excessive dose or after multiple small doses in which the cumulative dose exceeds 30 to 40 mg.²⁹ Treatment for this condition is variable and includes pain and paresthesia management with various medications, including opioids, nonsteroidal antiinflammatory drugs, cyclic antidepressants, vitamin E, and other drugs such as gabapentin and lamotrigine.²⁹ In a controlled clinical trial for vincristine-induced peripheral neuropathy, glutamic acid therapy had some efficacy. Patients receiving vincristine therapy were given glutamic acid as 500 mg orally three times a day.¹²⁴ There was a decreased incidence in loss of the Achilles tendon reflex and a delayed onset of paresthesias in the glutamic acid–treated group. No reported adverse events with glutamic acid were observed in this investigation. Animal studies involving the administration of glutamic and aspartic acid to mice poisoned with either vinblastine or vincristine demonstrate increased survival and decreased sensorimotor peripheral neuropathy.^{37,70,123} Although the exact mechanisms of these observed effects with glutamic acid remain unclear, several authors have suggested the ability of glutamic acid to competitively inhibit a common cellular transport mechanism

for vincristine.^{34,68} It may assist in the stabilization of tubulin and promote its polymerization into microtubules.^{39,108} Finally, glutamic acid may improve cellular metabolism by overcoming vinca alkaloid-associated inhibition in the Krebs cycle.^{82,125} Although the role of glutamic acid in acute toxicity needs further study, it is likely not harmful and should be considered. Glutamic acid may be initiated as 500 mg orally three times a day and should be continued for at least 5 days following exposure (approximately 95% of the drug should be eliminated after five half-lives) and possibly longer in very large exposures.^{124,174} L-Glutamic acid is the preferred stereoisomer because it is biologically active, and this product is available as a powder from various distributors in the United States.

Leucovorin may shorten the course of vincristine-induced peripheral neuropathy¹⁰⁴ and myelosuppression.¹³⁴ The mechanism is attributed to the ability of leucovorin to overcome the vincristine-mediated block of dihydrofolate reductase and thymidine synthetase.¹⁰⁴ However, neither leucovorin^{23,122,231} nor pyridoxine¹²² has been definitely shown to be effective. An initial experimental investigation evaluating the efficacy of antibody therapy to limit vinca alkaloid toxicity shows promise.¹⁰⁵ Unfortunately, vinca alkaloid specific antibodies for human poisoning are not commercially available.

The rapid distribution and high protein binding characteristics of vincristine favor early intervention with methods other than hemodialysis. Double-volume exchange transfusion was performed at 6 hours post-exposure in three children who were overdosed with 7.5 mg/m² of IV vincristine.¹³⁴ Of the two survivors, their respective postexchange serum vincristine concentrations were 57% and 71% lower than their preexchange concentrations. The amount of vincristine removed was not determined. Although these patients developed peripheral neuropathies, myelosuppression, and autonomic instability, the author noted that the duration of illness was shorter than previously reported. Thus, based on the pharmacokinetic profile of vincristine and these two reports, exchange transfusion in children is the preferred method of enhanced elimination when the patient presents soon after the administration of the drug, and plasmapheresis is the preferred method in adults.

Plasmapheresis was attempted with vinca alkaloid overdoses.^{142,189} In an 18 year-old patient who received two 8 mg IV doses of vincristine at 12 hour intervals, the procedure was performed 6 hours after the second dose, and 1.5 times the plasma volume was plasmapheresed.¹⁸⁹ Postplasmapheresis serum vincristine concentration was 23% lower than the starting concentration. The patient survived with myelosuppression, neurotoxicity, and SIADH.

One case of IV vinblastine overdose was reported to be successfully managed with plasma exchange procedures performed at 4 hours and 18 hours after vinblastine administration resulting in markedly less toxicity than what was expected.²¹⁹

Patients receiving an overdose of vincristine intravenously should be admitted to a cardiac-monitored bed and observed for 24 to 72 hours.¹⁴⁵ If patients remain asymptomatic during the observation period, then they can be discharged with follow-up for bone marrow suppression and SIADH; otherwise, depending on the patient's clinical condition, continual observation for progression of neurologic symptoms is warranted.²⁷

SUMMARY

- Colchicine toxicity manifests within several hours after ingestion and consists of severe nausea, vomiting, diarrhea, and abdominal pain followed by pancytopenia several days later.
- Colchicine poisoned patients are at risk of sudden cardiac death, especially during the period between 24 and 36 hours after ingestion; increasing serial troponin concentrations may be predictive of that risk.
- Podophyllum toxicity is less pronounced than colchicine toxicity but may occur after dermal application.
- When excessive doses of intravenously administered vincristine or vinblastine are likely to cause severe toxicity exchange transfusion, plasmapheresis and plasma exchange should be considered.
- Intrathecal administration of vincristine or vinblastine constitutes a life-threatening neurosurgical emergency.
- Management of patients with toxicity from ingested colchicine, podophyllotoxin, and vinca alkaloid derivatives is similar. Early GI decontamination and supportive treatment are the mainstays of therapy. G-CSF may be of benefit in patients who develop neutropenia.

37 NONSTEROIDAL ANTIINFLAMMATORY DRUGS

William J. Holubek

HISTORY AND EPIDEMIOLOGY

In the late 1800s, acetylsalicylic acid, aspirin, was shown to have antiinflammatory properties similar to those of corticosteroids when used in high doses in patients with rheumatoid arthritis. In a quest to develop a compound with antiinflammatory properties equivalent to corticosteroids but chemically nonsteroidal, Dr. Stewart Adams discovered and developed 2-(4-isobutylphenyl) propionic acid, now known as ibuprofen, and in the process created a new class of drugs designated as nonsteroidal antiinflammatory drugs (NSAIDs).³⁵ Ibuprofen was initially marketed in the United Kingdom in 1969 and was introduced to the US market in 1974. Ibuprofen became available without a prescription in the United States in 1984.

In addition to the numerous benefits of NSAIDs, some deleterious and life-threatening effects are associated with both their therapeutic use and overdose. In an attempt to circumvent some of these adverse effects, selective cyclooxygenase-2 (COX-2) inhibitors were developed, and in 1999, the first selective COX-2 inhibitor, rofecoxib, was approved by the US Food and Drug Administration (FDA), but it was withdrawn from the market in 2004 after postmarketing surveillance concluded an increase in myocardial infarctions and cerebrovascular accidents were associated with its use.

NSAIDs are considered among the most commonly used and prescribed medications in the world.^{10,72} An estimated one in seven patients with rheumatologic diseases is given a prescription for NSAIDs, and another one in five people in the United States use NSAIDs for acute common complaints.⁹⁴

Ibuprofen, naproxen, and ketoprofen are currently the only nonprescription NSAIDs in the United States. NSAIDs are also contained in cough and cold preparations and in prescription combination drugs (eg, ibuprofen with hydrocodone) and have occasionally been found as adulterants in herbal preparations.⁶²

The American Association of Poison Control Centers (AAPCC) compiles data regarding potentially toxic exposures called into participating poison centers throughout the United States using the National Poison Data System (NPDS) (Chap. 136). Beginning in 2006, a list of substances associated with the largest number of fatalities was reported annually, and since then NSAIDs have consistently been included in the top 25 substances.

The term NSAID used in this chapter does not refer to salicylates, which are unique members of the NSAID class and are covered in Chap. 39.

PHARMACOLOGY

These chemically heterogeneous compounds can be divided into carboxylic acid and enolic acid derivatives and COX-2 selective inhibitors (Table 37–1). They all share the ability to inhibit prostaglandin (PG) synthesis. PG synthesis begins with the activation of phospholipases (commonly, phospholipase A₂) that cleave phospholipids in the cell membrane to form arachidonic acid (AA). AA is metabolized by PG endoperoxide G/H synthase, otherwise known as COX, to form many eicosanoids, including PGs and the prostanoids, prostacyclin (PGI₂) and thromboxane A₂ (TXA₂). AA can also be metabolized by lipoxygenase (LOX) to form hydroperoxy eicosatetraenoic acid (HPETE), which is converted to many different leuko-trienes (LTs) that are involved in creating a proinflammatory environment (Fig. 37–1).

TABLE 37–1. Classes and Pharmacology of Selected Nonsteroidal Antiinflammatory Drugs^{8,17,18,29,56,64}

	<i>Time to Peak Plasma Concentration (hours)</i>	<i>Half-Life (hours)</i>	<i>Pharmacokinetics</i>	<i>Unique Features</i>
CARBOXYLIC ACIDS				
Acetic Acids				
Diclofenac ^{††}	2–3	1–2	First-pass effect; hepatic metabolism (CYP2C9)	Decreases leukocyte arachidonic acid concentration; topical activity; hepatotoxic
Etoricoxib	1	7	Hepatic metabolism	Inhibits leukocyte motility; coronary vasoconstrictor effect
Indomethacin	1–2	2.5	Demethylation (50%)	Poor antiinflammatory effect; topical activity
Ketorolac	<1	4–6	Urinary excretion	For parenteral use also
Sulindac	1–2	7	Active metabolite with a half-life of 18 hours	Prodrug; hepatotoxic
Tolmetin	<1	5	Hepatic metabolism	Accumulates in synovia
Fenamates				
Meclofenamate	0.5–2.0	2–3		Seizures; gastrointestinal inflammation
Mefenamic acid	2–4	3–4	Urinary excretion (50%)	Seizures; prostaglandin antagonist
Propionic Acids				
Fenoprofen	2	2–3	Decreased oral absorption (~85%)	Increased cerebrospinal fluid concentration
Flurbiprofen	1–2	6		Increased cerebrospinal fluid concentration
Ibuprofen ^{††}	<0.5	2–4	Hepatic metabolism; urinary excretion	Also formulated for parenteral use
Indobufen [†]	2	6–7	Urinary excretion (70%–80%)	In Europe, used as prophylaxis for thrombus formation
Ketoprofen [†]	1–2	2	Hepatic metabolism; urinary excretion	Bradykinin antagonist; stabilizes lysosomal membranes
Naproxen [†]	1	14	Increased half-life with kidney dysfunction	Inhibitory effect on leukocytes; prolonged platelet inhibition
Oxaprozin	3–6	40–60		Once-daily administration
Salicylates (Chap. 39)				
ENOLIC ACIDS				
Oxicams				
Meloxicam [†]	5–10	15–20		High Cyclooxygenase-2 selectivity
Nabumetone	3–6	24	Hepatic metabolism; active metabolites	Prodrug
Piroxicam	3–5	45–50	Hepatic metabolism (CYP2C9)	Inhibits neutrophil activation
Pyrazolone				
Phenylbutazone [†]	2	54–99	Hepatic metabolism; active metabolites	Irreversible agranulocytosis; aplastic anemia
CYCLOOXYGENASE-2 SELECTIVE INHIBITORS[†]				
Celecoxib	2–4	6–12	Hepatic metabolism (CYP2C9)	Inhibits CYP2D6
Limeciclib [†]	1–3	2–5	Urinary excretion (60%); active metabolites	Inhibits neutrophil activation

[†]COX-2 preferential. ^{††}Nonprescription. ^{†††}Not available in the United States for humans. ^{††††}Robicoxib (Vion) and valdecoxib (Dextra) are no longer available. ^{†††††}Available in combination with misoprostol. Available in combination with acetaminophen and hydrocodone.

FIGURE 37–1. Arachidonic acid (AA) metabolism. This figure also illustrates some of the major differences between cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). Phospholipase A (PCA) is stimulated by physical, chemical, inflammatory, and mitogenic stimuli and releases AA from cell membranes. The COX-1 enzyme synthesizes prostaglandins (PGs) that maintain cellular and vascular homeostasis. The COX-2 enzyme produces PGs within activated macrophages and endothelial cells that accompany inflammation. Whereas nonsteroidal antiinflammatory drugs (NSAIDs) reversibly inhibit both COX isoforms, selective COX-2 inhibitors inhibit the COX-2 isoform. Some authors suggest that inhibiting the COX enzymes shunts AA metabolism toward the production of chemotactic-vasoactive leukotrienes. Glucocorticoids inhibit PLA and down regulate induced expression of COX-2. ASA = acetylsalicylic acid; 5-HPETE, hydroperoxy eicosatetraenoic acid; GI = gastrointestinal; PGI₂ = prostacyclin; PGD = prostaglandin D; PGE₂ = prostaglandin E₂; PGF = prostaglandin F; PLT = platelet; RBF = renal blood flow; TXA₂ = thromboxane.

The COX enzyme responsible for PG production exists in two isoforms termed COX-1 and COX-2. COX-1 is constitutively expressed by virtually all cells throughout the body but is the only isoform found within platelets. This enzyme produces eicosanoids that govern “housekeeping” functions, including vascular homeostasis and hemostasis, gastric cytoprotection, and renal blood flow (RBF) and function.^{11,75} COX-2, on the other hand, is rapidly induced (within 1–3 hours) in inflammatory tissue by laminar shear (or mechanical) forces and cytokines, producing PGs involved in the inflammatory response. COX-2 is also upregulated by several cytokines, growth factors, and tumor promoters involved with cellular differentiation and mitogenesis, suggesting a role in cancer development.^{11,30,80}

Glucocorticoids can inhibit phospholipase A (PLA) and downregulate the induced expression of COX-2, which decreases the production of eicosanoids and PGs, respectively, but oral steroids are clinically not the first choice for an antiinflammatory drug regimen given their extensive adverse side effect profile, which includes osteoporosis, hyperglycemia, hypertension, glaucoma, muscle weakness, fluid retention, and mood swings. Most NSAIDs nonselectively inhibit the COX enzymes in a competitive or time-dependent, reversible manner, unlike salicylates, which irreversibly acetylate COX (Chap. 39). Inhibiting COX-1 can interrupt tissue homeostasis, leading to deleterious clinical effects. In what may seem advantageous, some NSAIDs (eg, etodolac, meloxicam, and nimesulide) preferentially inhibit COX-2 over COX-1, while others were specifically designed to selectively inhibit COX-2 (eg, celecoxib).⁹² As will be discussed later in this chapter, many of the selective COX-2 inhibitors (sometimes referred to as coxibs) were removed from the market in the United States because of their increased risk of adverse cardiovascular events.

NSAIDs do not directly affect LOX enzyme or the production of LTs; however, some data suggest that blocking the COX enzymes allows AA to be shunted toward the LOX pathway, increasing the production of proinflammatory and chemotactic-vasoactive LTs.^{54,94}

PHARMACOKINETICS AND TOXICOKINETICS

Most NSAIDs are organic acids with extensive protein binding (>90%) and small volumes of distribution of approximately 0.1 to 0.2 L/kg. Oral absorption of most NSAIDs occurs rapidly and near completely, resulting in bioavailabilities above 80%. Time to achieve peak plasma concentrations can vary widely (Table 37–1).¹⁶

Some NSAIDs possess unique characteristics regarding their sites of action and accumulation within the body. For example, whereas indomethacin, tolmetin, diclofenac, ibuprofen, and piroxicam achieve significant synovial concentrations, fenamates and indomethacin have both peripheral and central effects.¹⁶ NSAIDs have the ability to cross the blood–brain barrier, but the specific pharmacologic and physicochemical properties facilitating this ability are not well defined.^{3,55} Ketorolac and diclofenac have topical activity and are both used in ophthalmologic solutions, and diclofenac is also used in dermal preparations.¹⁶

Plasma half-lives in therapeutic dosing vary from as short as 1 to 2 hours for diclofenac and ibuprofen, to 50 to 60 hours for oxaprozin and piroxicam (Table 37–1). Most NSAIDs undergo hepatic metabolism with renal excretion of metabolites. Diclofenac undergoes extensive first-pass metabolism, only 10% to 20% of indomethacin and ketorolac are excreted unchanged in the urine. Variable amounts of NSAIDs are recovered in the feces.¹⁶

The kinetics of NSAIDs may change in overdose, depending on the particular xenobiotic. Therapeutic and supratherapeutic doses of naproxen (250 mg–4 g) result in the same half-life and time to peak plasma concentration, but the clearance and volume of distribution increase proportionately.^{65,74} When plasma protein binding of naproxen becomes saturated, the free drug concentration increases more rapidly than the total drug concentration, resulting in increased urinary excretion.⁷⁴ Overdoses of oral ibuprofen do not appear to prolong its elimination half-life.^{36,56,95}

PATHOPHYSIOLOGY

Gastrointestinal (GI) toxicity is the most common adverse effect from NSAID use (Table 37–2). Normally, the COX-1 enzyme expressed in the gastric epithelial cells leads to the production of PGs (PGE₂ and PGI₂), which are responsible for maintaining GI mucosal integrity by increasing mucous production and decreasing acid production. NSAIDs not only inhibit the production of these cytoprotective PGs and platelet aggregatory TXA₂ but also have a direct cytotoxic effect, increasing the risk of gastric and duodenal ulcers, perforations, and hemorrhage.^{23,68,72} Esophageal and small intestinal ulcers and strictures are also associated with NSAID use. Small intestinal diaphragms (or webs) are concentric weblike septa arising from submucosal fibrosis that can eventually cause a small bowel obstruction. These diaphragms rarely occur but are considered pathognomonic for NSAID use.²³

TABLE 37–2. Selected Adverse Effects of Nonsteroidal Antiinflammatory Drugs

Gastrointestinal

Chronic: dyspepsia, ulceration, perforation, hemorrhage, elevated hepatic aminotransferases, hepatocellular injury (rare)

Acute: same as above

Renal

Chronic: acute kidney failure, fluid and electrolyte retention, hyperkalemia, interstitial nephritis, nephrotic syndrome, papillary necrosis, azotemia

Acute: same as above

Hypersensitivity or Pulmonary

Chronic: angioedema, drug-induced lupus

Acute: asthma exacerbation, anaphylactoid and anaphylactic reactions, urticaria, angioedema, acute respiratory distress syndrome, drug-induced lupus

Hematologic

Chronic: increased bleeding time, agranulocytosis, aplastic anemia, thrombocytopenia, neutropenia, hemolytic anemia

Acute: same as above

Central Nervous System

Chronic: headache, dizziness, lethargy, coma, aseptic meningitis, delirium, cognitive dysfunction, hallucinations, psychosis

Acute: same as above

Drug Interactions

Aminoglycosides: increased risk of aminoglycoside toxicity⁷⁷

Anticoagulants (eg, warfarin, salicylates, heparins, direct thrombin inhibitors and Xa

inhibitors): increased risk of gastrointestinal bleeding^{11,76}

Antihypertensives (especially diuretics, β -adrenergic antagonists, and angiotensin-converting

enzyme inhibitors): reduced antihypertensive effects⁹⁵

Digoxin: increased risk of digoxin toxicity⁸⁵

Ethanol: increased bleeding time⁷⁶

Lithium: increased risk of lithium toxicity⁶⁸

Methotrexate: increased risk of methotrexate toxicity⁶⁸

Sulfonylureas: increased hypoglycemic effect⁸³

Selective COX-2 inhibitors decrease the incidence of significant GI toxicity compared with some nonselective NSAIDs, a benefit that is lost in patients concomitantly taking warfarin or low-dose aspirin.^{4,12,30,93} Although *Helicobacter pylori* and NSAID use both individually increase the risk of gastroduodenal ulcers, there are conflicting data regarding the relationship between the two, given the wide array of study designs, individual responses to infection and treatments, and different gastric acid suppressants. Current evidence suggests that the risk of GI toxicity may be decreased by eradicating *H. pylori* before initiating NSAID therapy in NSAID-naïve patients.^{10,18,23,72}

The kidney produces locally homeostatic PGs largely via COX-1, including PGI₂, PGE₂, and PGD₂, that maintain adequate glomerular filtration rate (GFR) and RBF and function by augmenting renal vasodilation, inhibiting sodium chloride absorption, and antagonizing the action of antidiuretic hormone (vasopressin). NSAIDs oppose this homeostatic

renal vasodilation and augment sodium reabsorption, blunting the antihypertensive effect of thiazide and loop diuretics. NSAIDs also decrease renin synthesis, a mechanism shared by β -adrenergic antagonists, rendering this antihypertensive therapy less effective.^{30,94} Patients with volume contraction (salt and water depletion) or poor cardiac output (congestive heart failure) have elevated concentrations of renal vasoconstrictor substances from stimulation of both the renin–angiotensin–aldosterone axis and the sympathetic nervous system, so NSAID use in these patients inhibits the synthesis of compensatory vasodilatory PGs, resulting in unopposed renal vasoconstriction and causing decreased RBF and GFR. This effect may lead to medullary ischemia and possibly acute kidney injury, particularly in elderly adults.⁷⁰ This vasoconstrictive effect is also associated with COX-2 selective inhibitors and appears to be reversible upon discontinuation of therapy.^{61,70,94}

Normal platelet function depends partly on endothelial-derived PGI₂ (largely via constitutively expressed COX-1), which blocks platelet activation and causes vasodilation, allowing blood to flow freely within vessels. At the site of vascular injury, platelets are activated by binding to collagen-bound von Willebrand factor and synthesize and release TXA₂, a potent platelet stimulator and vasoconstrictor. The antiplatelet activity of NSAIDs stems from their ability to inhibit COX-1, thereby inhibiting platelet-stimulating TXA₂ synthesis. Selective COX-2 inhibitors also decrease PGI₂ and TXA₂ synthesis but affect TXA₂ synthesis to a lesser degree, creating a more prothrombotic environment, which is the predominant theory of how selective COX-2 inhibitors increase the risk of adverse cardiovascular events (see below for further discussion).⁷⁵

Prostaglandins play a major role during the initiation of parturition. Administration of exogenous PGF_{2 α} and PGE₂ is used to induce uterine activity, and indomethacin has been used successfully as a tocolytic agent by blunting PG-mediated uterine stimulation. However, a major clinical drawback in using NSAIDs as tocolytics is their potential to cause premature constriction or closure of the ductus arteriosus in utero. Vasodilatory PGs are required to keep the fetal ductus arteriosus patent, and inhibiting these PGs causes fetal ductal constriction, leading to pulmonary hypertension and persistent fetal circulation after birth.⁵⁹

CARDIOVASCULAR RISK OF SELECTIVE CYCLOOXYGENASE-2 INHIBITORS AND NONSELECTIVE NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Atherosclerosis is a dynamic process of thrombus formation and inflammation involving numerous tissue factors and inflammatory mediators.³¹ Given the ability to inhibit synthesis of proinflammatory PGs, selective COX-2 inhibitors would be expected to be antithrombotic; however, their ability to inhibit endothelial-derived PGI₂ combined with their relative inability to inhibit platelet-activating TXA₂ (a predominantly COX-1 effect) may shift the balance toward thrombus formation.⁶⁰

In 2000, the Vioxx Gastrointestinal Outcomes Research (VIGOR) study reported a slightly higher incidence of myocardial infarction in patients taking rofecoxib compared with those taking naproxen (0.4% vs. 0.1%). This was thought to be because of a substantial number of patients who were not taking daily aspirin but should have been (based on FDA criteria) and that naproxen may have had a cardioprotective effect.^{12,57,60}

In 2004, Merck pharmaceutical company withdrew rofecoxib from the worldwide market given the prepublication results of a study demonstrating an undisputed elevated cardiovascular risk.¹⁴ Results from a meta-analysis⁴⁴ spawned controversy within the medical literature regarding the extent of delay before the withdrawal of rofecoxib from the market.^{26,42,48,86} Several other studies addressing selective COX-2 inhibitors had similarly increased risk of adverse cardiovascular events, suggesting this to be a class effect.^{26,66,81} Valdecoxib has subsequently been removed from the market, leaving celecoxib as the only selective COX-2 inhibitor available; however, it carries an FDA alert on a possible increased cardiovascular risk.⁸¹

The data on nonselective NSAID use and cardiovascular risk remain controversial. Many of the currently published studies and meta-analyses use large databases and are unable to exclude significant confounding factors, including smoking, body mass index, chronic disease, concurrent aspirin use, and socioeconomic status.⁹¹ Some of the nonselective NSAIDs that show a trend toward elevated cardiovascular risk include diclofenac, meloxicam, indomethacin, and, to a lesser extent, ibuprofen.^{33,57,77,91} In 2005, the FDA asked manufacturers of all nonprescription NSAIDs to revise their package inserts to provide more information on the potential cardiovascular risks pending further investigation.

CLINICAL MANIFESTATIONS

NSAIDs are a heterogeneous class of drugs, some carrying a unique toxicity profile. Fortunately, most nonselective

NSAIDs behave similarly in overdose, although much of the medical literature specifically describes ibuprofen. Regardless of the particular NSAID ingested, symptoms typically manifest within 4 hours after ingestion.^{36,37,38,53,56,90}

Initial clinical manifestations are usually mild and predominantly include GI symptoms, such as nausea, vomiting, or abdominal pain, or neurologic symptoms, such as drowsiness, headache, tinnitus, blurred vision, diplopia, and dizziness. More moderate and severe findings are rare and include coma, seizures, central nervous system (CNS) depression, metabolic acidosis, hypotension, hypothermia, rhabdomyolysis, electrolyte imbalances, cardiac dysrhythmias, and acute kidney injury.^{19,36,37,53,56,58,90} Massive NSAID ingestions may lead to multisystem organ failure and death.^{21,41,79,88,95}

Neurologic Effects

The neurologic effects of NSAID use vary from the mild drowsiness, headache, and dizziness with therapeutic dosing to the more life-threatening CNS depression, coma, and seizures in overdose. The mechanism associated with the decreased level of consciousness is unknown; however, several animal studies suggest a relationship with opioid receptors, and a human case report documents a dramatic return of consciousness in a child after intravenous (IV) administration of high-dose naloxone.²⁷ Other reported neurologic manifestations of toxicity include optic neuritis, amblyopia, color blindness, transient diplopia, other visual disturbances, transient loss of hearing, acute psychosis, and cognitive dysfunction.^{39,67}

Drug-induced aseptic meningitis is reported with several NSAIDs, including tolmetin, rofecoxib, naproxen, sulindac, piroxicam, and diclofenac, but ibuprofen is more commonly implicated, perhaps because of its widespread use.⁶⁴ Clinical findings include fever and chills, headache, meningeal signs, nausea, vomiting, and altered mental status; cerebrospinal fluid findings include pleocytosis, elevated protein, and normal glucose.⁶⁴ Studies suggest an immunologic mechanism behind NSAID-induced aseptic meningitis because it appears to be more common in patients with systemic lupus erythematosus (SLE) or mixed connective tissue disease.^{39,64,67}

Muscle twitching and generalized tonic-clonic seizures are described with mefenamic acid overdose and usually occur within 7 hours after ingestion.² Seizures are also associated with ibuprofen overdose,⁶⁹ although the specific mechanism for NSAID-induced seizures is unknown.

Renal and Electrolyte Effects

Both acute overdose and chronic therapeutic dosing of NSAIDs may have deleterious effects on kidney function, most of which are reversible. These include sodium retention and edema, hyperkalemia, acute kidney injury (AKI), membranous nephropathy, nephrotic syndrome, interstitial nephritis, and both acute and chronic renal papillary necrosis.^{39,71,94} General risk factors for NSAID-induced AKI include congestive heart failure, volume depletion, diabetes mellitus, underlying kidney disease, SLE, cirrhosis, diuretic therapy, and advanced age.⁵⁴ There is also growing concern over the potential development of AKI with NSAID use in patients who are concurrently taking multiple antihypertensive medications, such as diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers.⁵⁰

Acute tubulointerstitial nephritis (ATIN) is one of the more common forms of NSAID-induced renal impairment, and it may occur with short-term therapeutic dosing.^{24,54} Many cases of ATIN probably go undiagnosed because clinical symptoms usually do not appear until significant renal impairment occurs.^{24,73} Significant elevations in blood urea nitrogen (azotemia) may occur in elderly patients within 5 to 7 days of initiating NSAID therapy and usually return to baseline within 2 weeks of discontinuation.³⁴

Analgesic abuse nephropathy is a condition whose pathogenesis is not well defined, but it develops from excessive, chronic therapeutic consumption of NSAIDs. This results in AKI manifested by renal papillary necrosis, often requiring hemodialysis.^{78,94} Analgesic abuse nephropathy was originally described with the use of analgesic combinations including phenacetin and aspirin in addition to caffeine and has decreased in prevalence after the removal of phenacetin from many world markets.

Anion gap metabolic acidosis, with and without AKI, complicates many acute, massive ibuprofen ingestions and may be profound.^{25,41,95,96} The cause of the acidosis in this setting is most likely multifactorial, involving profound hypotension and tissue hypoperfusion with elevated lactate concentrations and the accumulation of ibuprofen and its two major metabolites, all weak acids.⁵³ An elevated anion gap metabolic acidosis with elevated lactate concentrations is also described after naproxen overdose, suggesting this to be a class effect given that all NSAIDs are acid derivatives.¹³

Use of NSAIDs by pregnant women is associated with reversible oligohydramnios and is used therapeutically as a treatment modality for polyhydramnios. Decreased fetal urine output and neonatal acute and chronic kidney failure, including transient oligoanuria, are associated with gestational NSAID use, commonly indomethacin.^{5,29,45}

Gastrointestinal Effects

Although the most common adverse GI effect of therapeutic NSAID use is dyspepsia, most patients with dyspepsia do not

have ulcers.²³ To help prevent the development of ulcers associated with NSAID therapy, concomitant use of misoprostol (a PGE₁ analog), an H₂-blocker, or a proton pump inhibitor (PPI) is often used; however, PPIs may be superior for both preventing and healing gastroduodenal ulcers resulting from chronic NSAID therapy.⁷² The most serious adverse GI effect is ulcer formation, which has the potential for life-threatening perforation and hemorrhage, and numerous studies reported an increased risk of these effects with therapeutic use of NSAIDs.^{32,51,68} The relative risk of developing gastroduodenal perforation, ulcer, or hemorrhage during chronic, therapeutic NSAID therapy ranges from 2.7 to 5.4, with ketorolac posing the greatest risk.^{68,87} Acute NSAID overdoses cause bloody emesis, fecal occult blood loss, and severe, life-threatening GI hemorrhage.

NSAID-induced hepatotoxicity is a well-known adverse effect that has prompted the removal of several NSAIDs from the market. Hepatotoxicity occurs with an incidence of less than 0.1% and can be quite difficult to diagnose because many patients on chronic NSAID therapy have underlying conditions, such as SLE or rheumatoid arthritis, which may cause hepatotoxicity. NSAID-induced hepatotoxicity is an idiosyncratic reaction primarily causing hepatocellular injury and does not depend on the chemical class. Diclofenac and sulindac are most commonly implicated.⁸⁵

Immunologic and Dermatologic Effects

The nonimmunologic anaphylactoid and the IgE-mediated anaphylactic reactions that are reported with the use of NSAIDs are clinically indistinguishable from one another, producing flushing, urticaria, bronchospasm, edema, and hypotension.⁷ Evidence for anaphylactic reactions includes the presence of NSAID-specific IgE antibodies, positive wheal-and-flare skin reactions, and lack of cross-reactivity with oral challenges of aspirin and other NSAIDs.⁷ The proposed mechanism of NSAID-induced anaphylactoid reactions involves the inhibition of COX-1, which not only inhibits the production of PGE₂ (which causes bronchodilation and inhibits the release of histamine from mast cells and basophils) but also shunts the AA metabolism to increased production of bronchoconstricting LTs.

The term aspirin-sensitive asthmatic is a bit of a misnomer because it refers to anaphylactoid reactions that may occur with any COX-1 inhibiting NSAID, not only aspirin.^{7,83} Selective COX-2 inhibitors cause similar clinical reactions but with an unclear mechanism. There appears to be very little cross-reactivity between NSAIDs and selective COX-2 inhibitors, and reports of reactions to one COX-2 inhibitor and not another suggest a predominant IgE-mediated mechanism.^{7,47,83}

The most common skin reactions include angioedema and facial swelling, urticaria and pruritus, bullous eruptions, and photosensitivity.³⁹ Although rare, toxic epidermal necrolysis and Stevens-Johnson syndrome are reported.³⁹

Hematologic Effects

As a class, NSAIDs are frequently implicated in the development of drug-induced thrombocytopenia and cause adverse effects on most other cell lines and function, including agranulocytosis, aplastic anemia, hemolytic anemia, methemoglobinemia, and pancytopenia.^{22,39,46,63,89} Specifically, phenylbutazone in chronic, therapeutic doses was associated with agranulocytosis and aplastic anemia,⁷⁹ prompting its removal from the US market in the 1970s. The inhibitory effect of NSAIDs on granulocyte adherence, activation, and phagocytosis, along with the potential for masking signs and symptoms, has been suggested as the mechanism responsible for the association between NSAID use and necrotizing fasciitis.⁴⁰

The ability of a particular type of NSAID to inhibit platelet aggregation and affect bleeding time depends on the dose and half-life because NSAIDs reversibly inhibit COX. One dose of ibuprofen prolongs the bleeding time within 2 hours and persists for up to 12 hours; however, this increase in bleeding time usually remains within the upper limit of normal range. This is in contrast to aspirin, which irreversibly inhibits COX, and typically doubles the bleeding time within 12 hours, returning to normal within 24 to 48 hours.⁷⁵ Compared with placebo, flurbiprofen and indobufen clinically inhibit platelet function, thereby decreasing vascular reocclusion after angioplasty and preventing thromboembolic complications.^{9,15} The concern over whether ketorolac has clinically significant effects on postoperative bleeding remains controversial.^{1,20}

NSAID use may also potentiate bleeding in patients already at higher risk. These patients include those with thrombocytopenia, coagulation factor deficiencies, or von Willebrand disease and those ingesting alcohol or on warfarin therapy.⁷⁵

Cardiovascular Effects

Although no evidence supports a direct cardiotoxic effect of NSAIDs or their metabolites, acute and massive NSAID overdoses may be complicated by persistent and severe hypotension; myocardial ischemia; and cardiac conduction abnormalities and dysrhythmias, including bradycardia, ventricular tachycardia or fibrillation, and prolonged QT

interval.^{25,41,95} The cause of these findings is yet to be elucidated, although these effects are reported only in severely ill patients with acid–base abnormalities and multisystem organ involvement (see Cardiovascular Risk earlier).

Pulmonary Effects

Although there is no evidence of direct pulmonary toxicity, some case reports describe the development of acute respiratory distress syndrome similar to the clinical manifestations of salicylate toxicity, suggesting an NSAID class mechanism based process.^{25,41,52,58} Although chest radiographic findings such as bilateral pulmonary infiltrates appear to resolve rapidly, one study reported persistent clinical abnormalities associated with exertional dyspnea one month later (see Immunologic Effects earlier).⁵⁸

Diagnostic Testing

Serum concentrations of most NSAIDs can be determined but usually only by a specialty laboratory requiring several days to report results. Although ibuprofen nomograms were constructed in an attempt to correlate serum concentrations with clinical toxicity,^{36,43} the utility of these nomograms proved limited.^{38,56}

Laboratory measurements, including complete blood count, serum electrolytes, blood urea nitrogen, and creatinine, should be obtained for all symptomatic patients, patients with intentional ingestions, ibuprofen ingestion of greater than 400 mg/kg in a child, or ibuprofen ingestion of greater than 6 g in an adult.³⁸ For patients presenting with significant neurologic effects, such as CNS depression, further evaluation of acid–base and ventilatory status by blood gas, hepatic aminotransferases, and prothrombin time should be obtained. A computed tomography scan of the head and a lumbar puncture may be clinically indicated in cases of suspected aseptic meningitis or when structural or infectious etiologies are suspected. An acetaminophen (APAP) concentration should always be determined in patients with intentional ingestions and in patients presenting with an unclear history because many people mistake APAP for NSAIDs because of confusing labeling and packaging or unawareness that they are completely different types of analgesics. For similar reasons, obtaining a salicylate concentration may also be considered.

MANAGEMENT

Management of a patient with an NSAID overdose is largely supportive and guided by the clinical signs and symptoms. Most asymptomatic patients with intentional overdose and those with normal vital signs require observation for 4 to 6 hours and a serum APAP concentration before being medically cleared. Children with ibuprofen ingestions of less than 100 mg/kg can be observed at home, but those who ingest greater than 400 mg/kg are at high risk for toxicity and require medical evaluation.³⁸ GI decontamination with activated charcoal (AC) should be considered for an asymptomatic patient with the potential for a large ingestion, symptomatic patients, and children with a history of ibuprofen ingestion greater than 400 mg/kg.^{38,49} Serum concentrations of ibuprofen continue to increase even after the time of emergency department arrival, so gastric lavage for massive overdose followed by AC should be considered, and multiple-dose AC may be useful for patients with massive overdoses of sustained-release preparations.⁹⁵

Patients who develop severe, life-threatening manifestations usually present with lethargy or unresponsiveness.^{25,41,58,69,95} Aggressive, supportive care is indicated in these patients, including stabilization of the airway and IV fluid therapy. An early electrocardiogram is essential to detect any significant electrolyte abnormalities or conduction disturbances. Electrolyte imbalances should be corrected and sodium bicarbonate therapy considered for life-threatening metabolic acidosis. Hypotension should be treated initially with IV fluid therapy followed by direct-acting vasopressors if necessary. Electrocardiograms should be monitored for the development of any life-threatening electrolyte imbalances or cardiac conduction abnormalities.

Given their high protein binding, NSAIDs do not appear to be amenable to extracorporeal removal methods; however, in cases of refractory metabolic acidosis or kidney failure, hemodialysis or continuous renal replacement therapies may be useful to correct the acid–base status.^{6,52} Patients with seizures, which are characteristic of mefenamic acid overdose,² should be treated with IV benzodiazepines.

SUMMARY

- NSAIDs are among the most commonly used drugs in the world.
- Most patients with NSAID overdoses develop nonspecific symptoms, including nausea and abdominal discomfort, requiring little clinical management other than psychiatric assessment.
- Patients with large ingestions may require GI decontamination and treatment of metabolic acidosis and kidney failure.
- In all cases of intentional NSAID ingestion, APAP coingestion should be excluded.

38 OPIOIDS

Lewis S. Nelson and Dean Olsen

Opioids are among the oldest therapies in our armamentarium, and clinicians recognize their universal utility to limit human distress from pain. Opioids enjoy widespread use as potent analgesics, even though they are abused because of their psychoactive properties. Although the therapeutic and toxic doses are difficult to predict because of the development of tolerance with chronic use, the primary adverse event from excessive dosing is respiratory depression.

HISTORY AND EPIDEMIOLOGY

The medicinal value of opium, the dried extract of the poppy plant *Papaver somniferum*, was first recorded around 1500 B.C. in the Ebers papyrus. Raw opium is typically composed of at least 10% morphine, but extensive variability exists depending on the environment in which the poppy is grown.⁸⁹ Although reformulated as laudanum (deodorized tincture of opium; 10 mg morphine/mL) by Paracelsus, paregoric (camphorated tincture of opium; 0.4 mg morphine/mL), Dover's powder (pulvis Doveri), and Godfrey's cordial in later centuries, the contents remained largely the same: phenanthrene poppy derivatives, such as morphine and codeine. Over the centuries since the Ebers papyrus, opium and its components have been exploited in two distinct manners: medically to produce profound analgesia and nonmedically to produce psychoactive effects.

Currently, the widest clinical application of opioids is for acute or chronic pain relief. Opioids are available in various formulations that allow administration by virtually any route: epidural, inhalational, intranasal, intrathecal, oral, parenteral (ie, subcutaneous {SC}, intravenous {IV}, intramuscular {IM}), rectal, transdermal, and transmucosal. Patients also may benefit from several of the nonanalgesic effects engendered by certain opioids. For example, codeine and hydrocodone are widely used as antitussives, and diphenoxylate is used as an antidiarrheal.

Unfortunately, the history of opium and its derivatives is marred by humankind's endless quest for xenobiotics that produce pleasurable effects. Opium smoking was so problematic in China by the 1830s that the Chinese government attempted to prohibit the importation of opium by the British East India Company. This act led to the Opium Wars between China and Britain. China eventually accepted the importation and sale of the drug and was forced to turn over Hong Kong to British rule. The euphoric and addictive potential of the opioids is immortalized in the works of several famous writers, such as Thomas de Quincey (*Confessions of an English Opium Eater*, 1821), Samuel Coleridge (*The Rime of the Ancient Mariner*, 1798), and Elizabeth Barrett Browning (*Aurora Leigh*, 1856).

Because of mounting concerns of addiction and toxicity in the United States, the Harrison Narcotic Act, enacted in 1914, made nonmedicinal use of opioids illegal. Since that time, recreational and habitual use of heroin and other opioids have remained epidemic in the United States and worldwide despite extensive and diverse attempts to curb their availability.

Morphine was isolated from opium by Armand Séguin in 1804. Charles Alder Wright synthesized heroin from morphine in 1874. Ironically, the development and marketing of heroin as an antitussive agent by Bayer, the German pharmaceutical company, in 1898 legitimized the medicinal role of heroin.¹⁶⁵ Subsequently, various xenobiotics with opioidlike effects were marketed, each promoted for its presumed advantages over morphine. This assertion proved true for fentanyl because of its pharmacokinetic profile. However, in general, the advantages of such medications have fallen short of expectations, particularly with regard to their potential for abuse.

Prescription drug abuse (use for psychoactive effects) and misuse (eg, use of someone else's medication) is among the leading causes of death in the United States, and the opioid analgesics account for approximately 80% of these outcomes. Although media reports highlight the abuse of prescription opioids by sports figures and other personalities, such use has reached epidemic levels in regions of the country where heroin is difficult to obtain (thus the term "hillbilly heroin"). In 2009, deaths from prescription drugs, mainly opioids, first exceeded those from motor vehicle crashes.²¹ The abuse liabilities of these semisynthetic opioids, based on their subjective profile, are similar.¹⁸⁷ Although many users initially receive oxycodone or hydrocodone as analgesics, the majority of abusers obtain the drugs illicitly or from friends.^{14,67} Regulatory agencies (such as the Food and Drug Administration {FDA} through Risk Evaluation and Mitigation Strategies or REMS)¹²⁶ and individual states through prescription drug monitoring programs,¹³³ law enforcement, and the drug manufacturer have made tremendous efforts to control drug diversion to illicit use.^{64,182} Physicians and pharmacists have been charged criminally with complicity for inappropriate prescribing and dispensing, respectively, for patients with the intent to sell or abuse these drugs.⁶⁴ As supplies of the prescription opioids fall, some abusers are turning to heroin, which is easily available and less expensive, as a substitute, but carries distinct risk.²⁵

Over the past decade and along with the realization that opioid analgesics are subject to abuse and misuse, newer formulations of existing opioids have attempted to be recognized for their reduced abuse potential.²⁵ In general, this has been through the use of tamper resistant formulations that reduce the abuser's ability to crush or dissolve the tablet for insufflation or injection, respectively.¹⁴⁹ However, the true benefit of such formulations is not known, and the majority of abusers ingest their medications whole, suggesting that the overall benefit will be limited.

The terminology used in this chapter recognizes the broad range of xenobiotics commonly considered to be opiumlike. The term opiate specifically refers to the relevant alkaloids naturally derived directly from the opium poppy: morphine; codeine; and, to some extent, thebaine and noscapine. Opioids are a much broader class of xenobiotics that are capable of either producing opiumlike effects or binding to opioid receptors. A semisynthetic opioid, such as heroin or oxycodone, is created by chemical modification of an opiate. A synthetic opioid is a chemical, that is not derived from an opiate, and is capable of binding to an opioid receptor and producing opioid effects clinically. Synthetic opioids, such as methadone and meperidine, bear little structural similarity to the opiates. Opioids also include the naturally occurring animal derived opioid peptides such as endorphin and nociceptin/orphanin FQ. The term narcotic refers to sleep-inducing xenobiotics and initially was used to connote the opioids. However, law enforcement and the public currently use the term to indicate any illicit psychoactive substance. The term opioid as used hereafter encompasses the opioids and the opiates.

PHARMACOLOGY

Opioid Receptor Subtypes

Despite nearly a century of opioid studies, the existence of specific opioid receptors was not proposed until the mid-20th century. Beckett and Casy noted a pronounced stereospecificity of existing opioids (only the L-isomer is active) and postulated that the drug needed to "fit" into a receptor.⁸ In 1963, after studies on the clinical interactions of nalorphine and morphine, the theory of receptor dualism¹⁶⁷ postulated the existence of two classes of opioid receptors. Such opioid binding sites were not demonstrated experimentally until 1973.¹³⁴ Intensive experimental scrutiny using selective agonists and antagonists continues to permit refinement of receptor classification. The current, widely accepted schema postulates the coexistence of three major classes of opioid receptors, each with multiple subtypes, and several poorly defined minor classes.

Initially, the reason such an elaborate system of receptors existed was unclear because no endogenous ligand could be identified. However, evidence for the existence of such endogenous ligands was uncovered in 1975 with the discovery of met-enkephalin and leu-enkephalin¹⁰⁸ and the subsequent identification of β -endorphin and dynorphin. As a group, these endogenous ligands for the opioid receptors are called endorphins (endogenous morphine). Each is a five amino acid peptide cleaved from a larger precursor peptide: pro-enkephalin, pro-opiomelanocortin, and prodynorphin, respectively. More recently, a minor related endogenous opioid (nociceptin/orphanin FQ) and its receptor ORL have been described.

All three major opioid receptors have been cloned and sequenced. Each consists of seven transmembrane segments, an amino terminus, and a carboxy terminus. Significant sequence homology exists between the transmembrane regions of opioid receptors and those of other members of the guanosine triphosphate (GTP)-binding protein (G-protein)-binding receptor superfamily. However, the extracellular and intracellular segments differ from one another. These nonhomologous segments probably represent the ligand binding and signal transduction regions, respectively, which would be expected to differ among the three classes of receptors. The individual receptors have distinct distribution patterns within the central nervous system (CNS) and peripherally on nerve endings within various tissues, mediating unique but not entirely understood clinical effects. Until recently, researchers used varying combinations of agonists and antagonists to pharmacologically distinguish between the different receptor subtypes. However, knockout mice (ie, mutant mice lacking the genes for an individual opioid receptor) promise new insights into this complex subject.⁵⁷

Because multiple opioid receptors exist and each elicits a different effect, determining the receptor to which an opioid preferentially binds should allow prediction of the clinical effect of the opioid. However, binding typically is not limited to one receptor type, and the relative affinity of an opioid for differing receptors accounts for the clinical effects (Table 38–1). Even the endogenous opioid peptides exhibit substantial crossover among the receptors.

TABLE 38–1. Clinical Effects Related to Opioid Receptors

<i>1996 Conventional Name</i>	<i>Proposed IUPHAR Name</i>	<i>IUPHAR Name</i>	<i>Important Clinical Effects of Receptor Agonists</i>
μ_1	OP _{3a}	MOP	Supraspinal analgesia Peripheral analgesia Sedation Euphoria Prolactin release
μ_2	OP _{3b}		Spinal analgesia Respiratory depression Physical dependence Gastrointestinal dysmotility Pruritus Bradycardia Growth hormone release
κ_1	OP _{2a}	KOP	Spinal analgesia Miosis Diuresis
κ_2	OP _{2b}		Psychotomimesis Dysphoria
κ_3	OP _{2b}		Supraspinal analgesia
δ	OP ₁	DOP	Spinal and supraspinal analgesia Modulation of μ -receptor function Inhibit release of dopamine
Nociceptin/ orphanin FQ	OP ₄	NOP	Anxiolysis Analgesia

IUPHAR = International Union of Pharmacology Committee on Receptor Nomenclature.

Although the familiar pharmacologic nomenclature derived from the Greek alphabet is used throughout this textbook, the International Union of Pharmacology (IUPHAR) Committee on Receptor Nomenclature has twice recommended a nomenclature change from the original Greek symbol system to make opioid receptor names more consistent with those of other neurotransmitter systems.¹⁸⁵ In the first new schema, the receptors were denoted by their endogenous ligand (opioid peptide {OP}), with a subscript identifying their chronologic order of discovery.⁴² The δ receptor was renamed OP₁, the δ receptor was renamed OP₂, and the μ receptor was renamed OP₃. However, adoption of this nomenclature met with significant resistance, presumably because of problems that would arise when merging previously published work that had used the Greek symbol nomenclature. The currently proposed nomenclature suggests the addition of a single letter in front of the OP designation and the elimination of the number. In this schema, the μ receptor is identified as MOP. In addition, the latest iteration formally recognizes the nociceptin/orphanin FQ or NOP receptor as a fourth receptor family.

Mu Receptor (μ , MOP, OP₃). The early identification of the μ receptor as the morphine binding site gave this receptor its designation.¹¹³ Although many exogenous xenobiotics produce supraspinal analgesia via μ receptors, the endogenous ligand is elusive. Nearly all of the recognized endogenous opioids have some affinity for the μ receptor, although none is selective for the receptor. Endomorphin-1 and –2 are nonpeptide ligands present in brain that may represent the endogenous ligand.

Experimentally, two subtypes (μ_1 and μ_2) are well defined, although currently no xenobiotics have sufficient selectivity to make this dichotomy clinically relevant. Experiments with knockout mice suggest that both subtypes derive from the same gene and that either posttranslational changes or local cellular effects subsequently differentiate them. The μ_1 subtype appears to be responsible for supraspinal (brain) analgesia and for the euphoria engendered by these xenobiotics. Although stimulation of the μ_2 subtype produces spinal-level analgesia, it also produces respiratory depression. All of the currently available μ agonists have some activity at the μ_2 receptor and therefore produce some degree of respiratory compromise. Localization of μ receptors to regions of the brain involved in analgesia (periaqueductal gray, nucleus raphe magnus, medial thalamus), euphoria and reward (mesolimbic system), and respiratory function (medulla) is not unexpected.⁷³ Predictably, μ receptors are found in the medullary cough center; peripherally in the gastrointestinal (GI) tract; and on various sensory nerve endings, including the articular surfaces (see analgesia under Clinical Manifestations below).

Kappa Receptor (κ , KOP, OP_2). Although dynorphins now are known to be the endogenous ligands for these receptors, originally they were identified by their ability to bind ketocyclazocine and thus were labeled δ .¹¹³ Receptors exist predominantly in the spinal cords of higher animals, but they also are found in the antinociceptive regions of the brain and the substantia nigra. Stimulation is responsible for spinal analgesia, miosis, and diuresis (via inhibition of antidiuretic hormone release). Unlike μ -receptor stimulation, δ -receptor stimulation is not associated with significant respiratory depression or constipation. The receptor currently is subclassified into three subtypes. The δ_1 receptor subtype is responsible for spinal analgesia. This analgesia is not reversed by μ -selective antagonists,¹²⁰ supporting the role of δ receptors as independent mediators of analgesia. Although the function of the δ_2 receptor subtype is largely unknown, stimulation of cerebral δ_2 receptors by xenobiotics such as pentazocine and salvinorin A produces psychotomimesis in distinction to the euphoria evoked by μ agonists.¹⁵⁸ The δ_3 receptor subtype is found throughout the brain and participates in supraspinal analgesia. This receptor is primarily responsible for the action of nalorphine, an agonist–antagonist opioid. Nalbuphine, another agonist–antagonist, exerts its analgesic effect via both δ_1 and δ_3 agonism, although both nalorphine and nalbuphine are antagonists to morphine at the μ receptor.¹³⁶

Delta Receptor (δ , DOP, OP_1). Little is known about δ receptors, although the enkephalins are known to be their endogenous ligands. Opioid peptides identified in the skin and brain of *Phyllomedusa* frogs, termed dermorphin and deltorphin, respectively, are potent agonists at the δ receptor. δ Receptors may be important in spinal and supraspinal analgesia (probably via a noncompetitive interaction with the μ receptor) and in cough suppression. δ Receptors may mediate dopamine release from the nigro-striatal pathway, where they modulate the motor activity associated with amphetamine.⁷⁴ δ Receptors do not modulate dopamine in the mesolimbic tracts and have only a slight behavioral reinforcing role. Subpopulations, specifically δ_1 and δ_2 , are postulated based on in vitro studies but presently are not confirmed in vivo.¹⁸⁵

Nociceptin/Orphanin FQ Receptor (ORL_1 , NOP, OP_4). The ORL_1 receptor was identified in 1994 based on sequence homology during screening for opioid-receptor genes with DNA libraries. It has a similar distribution pattern in the brain and uses similar transduction mechanisms as the other opioid-receptor subtypes. It binds many different opioid agonists and antagonists. Its insensitivity to antagonism by naloxone, often considered the sine qua non of opioid character, delayed its acceptance as an opioid-receptor subtype. Simultaneous identification of an endogenous ligand, called nociceptin by the French discoverers and orphanin FQ by the Swiss investigators, allowed the designation OP_4 . A clinical role has not yet been defined, but anxiolytic and analgesic properties are described.²⁹

Opioid-Receptor Signal Transduction Mechanisms

Figure 38–1 illustrates opioid-receptor signal transduction mechanisms. Continuing research on the mechanisms by which an opioid receptor induces an effect has produced confusing and often contradictory results. Despite the initial theory that each receptor subtype is linked to a specific transduction mechanism, individual receptor subtypes may use one or more mechanisms, depending on several factors, including receptor localization (eg, presynaptic vs postsynaptic). As noted, all opioid-receptor subtypes are members of a superfamily of membrane-bound receptors that are coupled to G proteins.¹⁸⁵ The G proteins are responsible for signaling the cell that the receptor is activated and for initiating the desired cellular effects. The G proteins are generally of the pertussis toxin-sensitive, inhibitory subtype known as G_i or G_o , although coupling to a cholera toxin-sensitive, excitatory G_s subtype has been described. Regardless of subsequent effect, the G proteins consist of three conjoined subunits, α , β , and γ . The $\beta\gamma$ subunit is liberated upon GTP binding to the subunit. When the α subunit dissociates from the $\beta\gamma$ subunit, it modifies specific effector systems, such as phospholipase C or adenylate cyclase, or it may directly affect a channel or transport protein. GTP subsequently is hydrolyzed by a GTPase intrinsic to the α subunit, which prompts its reassociation with the $\beta\gamma$ subunit and termination of the receptor-mediated effect.

FIGURE 38–1. Opioid-receptor signal transduction mechanisms. Upon binding of an opioid agonist to an opioid receptor, the respective G protein is activated. G proteins may reduce the capacity of adenylate cyclase to produce cyclic adenosine monophosphate (cAMP) (A); close calcium channels that reduce the signal to release neurotransmitters (B); or open potassium channels and hyperpolarize the cell, which indirectly reduces cell activity (C). Each mechanism has been found coupled to each receptor subtype, depending on the location of the receptor (pre- or postsynaptic), and the neuron within the brain (see text). Note that α_2 receptors (D) mediate similar effects, using a different G protein (G_z).

(A) Adenylate cyclase/cAMP. Inhibition of adenylate cyclase activity by G_i or G_o is the classic mechanism for postsynaptic signal transduction invoked by the inhibitory μ receptors. However, this same mechanism also has been identified in cells bearing either δ or δ receptors. Activation of cAMP production by adenylate cyclase, with subsequent activation of protein kinase A, occurs after exposure to very-low-dose opioid agonists and produces excitatory, antianalgesic effects.⁴⁴

(B) Calcium (Ca^{2+}) channels. Presynaptic μ receptors inhibit norepinephrine release from the nerve terminals of cells of the rat cerebral cortex. Adenylate cyclase does not appear to be the modulator for these receptors because inhibition of norepinephrine release is not enhanced by increasing intracellular cAMP levels by various methods. Opioid-induced blockade is, however, prevented by increased intracellular calcium levels that are induced either by calcium ionophores, which increase membrane permeability to calcium, or by increasing the extracellular calcium concentration. This implies a role for opioid-induced closure of N-type calcium channels, presumably via a G_o protein. Reduced intraterminal concentrations of calcium prevent the neurotransmitter-laden vesicles from binding to the terminal membrane and releasing their contents. Nerve terminals containing dopamine appear to have an analogous relationship with inhibitory δ receptors, as do acetylcholine-bearing neurons with opioid receptors.

(C) Potassium (K^+) channels. Increased conductance through a potassium channel, generally mediated by G_i or G_o , results

in membrane hyperpolarization with reduced neuronal excitability. Alternatively, protein kinase A mediated reduction in membrane potassium conductance enhances neuronal excitability. ATP = adenosine triphosphate.

CLINICAL MANIFESTATIONS

Table 38–2 outlines the clinical effects of opioids.

TABLE 38–2. Clinical Effects of Opioids

Cardiovascular	Bradycardia Orthostatic hypotension Peripheral vasodilation
Dermatologic	Flushing (histamine) Pruritus
Endocrinologic	Reduced antidiuretic hormone release Increased prolactin release Reduced gonadotrophin release
Gastrointestinal	Increased anal sphincter tone Increased biliary tract pressure Reduced gastric acid secretion Reduced motility
Neurologic	Analgesia Antitussive Euphoria Sedation, coma Seizures (meperidine, propoxyphene)
Ophthalmic	Miosis
Pulmonary	Acute respiratory distress syndrome Bronchospasm (histamine) Respiratory depression

Therapeutic Effects

Analgesia. Although classic teaching attributes opioid analgesia solely to the brain, opioids actually appear to modulate cerebral cortical pain perception at supraspinal, spinal, and peripheral levels. The regional distribution of the opioid receptors confirms that μ receptors are responsible for most of the analgesic effects of morphine within the brain. They are found in highest concentration within areas of the brain classically associated with analgesia—the periaqueductal gray, nucleus raphe magnus, locus ceruleus, and medial thalamus. Microelectrode-induced electrical stimulation of these areas¹⁴¹ or iontophoretic application of agonists into these regions results in profound analgesia.¹⁰ Specifically, enhancement of inhibitory outflow from these supraspinal areas to the sensory nuclei of the spinal cord (dorsal roots) dampens nociceptive neurotransmission. Additionally, inactivation of the μ opioid receptor gene in embryonic mouse cells results in offspring that are insensitive to morphine analgesia.¹¹⁴

Interestingly, blockade of the N-methyl-D-aspartate (NMDA) receptor, a mediator of excitatory neurotransmission, enhances the analgesic effects of μ opioid agonists and may reduce the development of tolerance (see dextromethorphan later).¹ Even more intriguing is the finding that low dose naloxone (0.25 $\mu\text{g/kg/h}$) actually improves the efficacy of morphine analgesia.⁵⁴ Administration of higher dose, but still low dose, naloxone (1 $\mu\text{g/kg/h}$) obliterated its opioid-sparing effect. Although undefined, the mechanism may be related to selective inhibition of G_s -coupled excitatory opioid receptors by extremely low concentrations of opioid receptor antagonist.^{31,32}

Xenobiotics with strong binding affinity for δ receptors in humans produce significantly more analgesia than morphine administered intrathecally. Indeed, the use of spinal and epidural opioid analgesia is predicated on the direct administration of opioid near the δ and δ receptors in the spinal cord. Agonist–antagonist opioids, with agonist affinity for the δ receptor and antagonist effects at the μ receptor, maintain analgesic efficacy.

Interestingly, communication between the immune system and the peripheral sensory nerves occurs in areas of tissue inflammation. In response to inflammatory mediators, such as interleukin-1, immune cells locally release opioid peptides, which bind and activate peripheral opioid receptors on sensory nerve terminals.¹⁸⁶ Agonism at these receptors reduces afferent pain neurotransmission and may inhibit the release of other proinflammatory compounds, such as substance P.¹⁶⁸ Of note, intraarticular morphine (1 mg) administered to patients after arthroscopic knee surgery produces significant, long lasting analgesia that can be prevented with intraarticular naloxone.¹⁶⁹ The clinical analgesic effect of 5 mg of intraarticular morphine is equivalent to 5 mg of morphine given IM.²⁴ Intraarticular analgesia is locally mediated by μ receptors.⁵⁰

The data to support the safety and efficacy of opioids for the management of chronic pain are limited. Addiction and dependence, which share a complicated relationship and often overlap with pain and depression, occur in at least 5% of patients using classical definitions, but other studies suggest it may be as high as 30%.¹²³ The pleasurable effects of many xenobiotics used by humans are mediated by the release of dopamine in the mesolimbic system. This final common pathway is shared by all opioids that activate the μ - δ receptor complex in the ventral tegmental area, which, in turn, indirectly promotes dopamine release in the mesolimbic region. Opioids also may have a direct reinforcing effect on their self administration through μ receptors within the mesolimbic system.⁷²

The sense of well being and euphoria associated with strenuous exercise appears to be mediated by endogenous opioid peptides and μ receptors. This so-called “runner’s high” is reversible with naloxone.¹⁵⁶ Naloxone may also reverse euphoria or even produce dysphoria in nonexercising, highly trained athletes. Even in normal individuals, high dose naloxone (4 mg/kg) may produce dysphoria.²⁶

Exogenous opioids do not induce uniform psychological effects. Some of the exogenous opioids, particularly those that are highly lipophilic such as heroin, are euphorogenic, but morphine is largely devoid of such pleasurable effects.¹⁶³ However, morphine administration results in analgesia, anxiolysis, and sedation. Because heroin has little affinity for opioid receptors and must be deacetylated to morphine for effect, these seemingly incompatible properties likely are related to pharmacokinetic differences in blood–brain barrier penetration.¹³⁰ Chronic users note that fentanyl produces effects that are subjectively similar to those of heroin.¹⁰² This effect may explain the higher prevalence of fentanyl, as opposed to other accessible opioids, as an abused drug by anesthesiologists.^{12,189} In distinction, certain opioids, such as pentazocine, produce dysphoria, an effect that is related to their affinity for δ or σ receptors.

Chronic use of opioid analgesics is associated with hyperalgesia, or a heightened sensitivity to pain.²⁷ This effect was described decades ago in methadone maintenance patients⁷⁶ and has been revisited as the use of chronic opioid therapy for pain has increased.¹⁸ Hyperalgesia may be part of the development of tolerance or the need for increasing amount of opioid to maintain a stable level of analgesia, but the treatment for hyperalgesia should include attempts at alternative modalities of pain relief.

Antitussive. Codeine and dextromethorphan are two opioids with cough suppressant activity. Cough suppression is not likely mediated via the μ_1 opioid receptor because the ability of other opioids to suppress the medullary cough centers is not correlated with their analgesic effect. Various models suggest that cough suppression occurs via agonism of the μ_2 or δ opioid receptors or antagonism of the δ opioid receptor and that the σ or NMDA receptors also are involved.¹⁷⁵

Toxic Effects

When used appropriately for medical purposes, opioids are generally safe and effective. However, excessive dosing for any reason may result in serious toxicity. Most adverse or toxic effects are predictable based on opioid pharmacodynamics (eg, respiratory depression), although several xenobiotics produce unexpected “nonopioid” or xenobiotic-specific responses. Determining that a patient has an opioid toxicity is generally more important than identifying the specific opioid involved. Notwithstanding some minor variations, patients poisoned by all available opioids predictably develop a constellation of signs, known as the opioid syndrome (**Chap. 3**). Mental status depression, hypoventilation, miosis, and hypoperistalsis are the classic elements.

Respiratory Depression. Experimental use of various opioid agonists and antagonists consistently implicates μ_2 receptors in the respiratory depressant effects of morphine.¹⁵⁸ Through these receptors, opioid agonists reduce ventilation by diminishing the sensitivity of the medullary chemoreceptors to hypercapnea.¹⁹² In addition to loss of hypercarbic stimulation, opioids depress the ventilatory response to hypoxia.¹⁰³ The combined loss of hypercarbic and hypoxic drive leaves virtually no stimulus to breathe, and apnea ensues. Equianalgesic doses of the available opioid agonists produce approximately the same degree of respiratory depression.^{47,159} This reasoning is supported by experiments in MOR deficient knockout mice.¹⁴⁵ Patients chronically exposed to opioid agonists, such as those on methadone maintenance, experience chronic hypoventilation, although tolerance to loss of hypercarbic drive may develop over several months.¹¹¹ However, such patients never develop complete tolerance to loss of hypoxic stimulation.¹⁴⁷ Although some opioids, notably the agonist–antagonists and partial agonists, typically demonstrate a ceiling effect on respiratory depression, such sparing generally occurs at the expense of analgesic potency and is incomplete. The different activity profiles likely are a

result of differential activities at the opioid-receptor subtypes; that is, agonist–antagonists are predominantly δ -receptor agonists and either partial agonists or antagonists at μ sites.

It is important to recognize that ventilatory depression may be secondary to a reduction in either respiratory rate or tidal volume. Thus, although respiratory rate is more accessible for clinical measurement, it is not an ideal index of ventilatory depression. In fact, morphine-induced respiratory depression in humans initially is related more closely to changes in tidal volume.¹⁵⁹ Large doses of opioids also result in a reduction of respiratory rate.

Respiratory depression is the primary cause of death after therapeutic use or misuse. Common reasons for iatrogenic overdose include not appreciating the importance of genetic polymorphisms (see Codeine), sleep apnea, drug interactions, active metabolites (see Morphine), or the complicated pharmacokinetics of the long-acting and sustained-release opioids.¹²⁸

Acute Respiratory Distress Syndrome (ARDS). Reports linking opioids with the development of acute pulmonary abnormalities became common in the 1960s, although the first report was made by William Osler in 1880.¹³² Almost all opioids are implicated, and opioid-related acute respiratory distress syndrome is reported in diverse clinical situations. Typically, the patient regains normal ventilation after a period of profound respiratory depression, either spontaneously or after the administration of an opioid antagonist, and over the subsequent several minutes to hours develops hypoxemia and pulmonary crackles. Occasionally, classic frothy, pink sputum is present in the patient's airway or in the endotracheal tube of an intubated patient. Decedents often have what is described as a "foam cone" of frothy material extruding from their noses and mouths. Acute lung injury (ALI) was described in 71 (48%) of 149 hospitalized heroin overdose patients in New York City,⁴⁵ although the current incidence in this patient group appears to be lower. The outcome generally depends on comorbid conditions and the delay to adequate care. ALI may be an isolated finding or may occur in the setting of multisystem organ damage.

No single mechanism can be consistently invoked in the genesis of opioid associated ARDS. However, several prominent theories are each well supported by experimental data. Rather than causing ARDS, naloxone likely "uncovered" the clinical findings of ARDS that were not evident because an adequate examination could not be performed until breathing is restored. Other evidentiary cases involve surgical patients given naloxone postoperatively who subsequently awoke with clinical signs of pulmonary edema. In addition to presumably receiving the naloxone for ventilatory compromise or hypoxia, these patients received multiple intraoperative medications, further obscuring the etiology.¹³⁷ Although naloxone ordinarily is safe when appropriately administered to nonopioid tolerant individuals, the production of acute opioid withdrawal may be responsible for "naloxone-induced" ARDS. In this situation, as in patients with "neurogenic" pulmonary edema, massive sympathetic discharge from the CNS occurs and produces "cardiogenic" pulmonary edema from the acute effects of catecholamines on the myocardium. In an interesting series of experiments, precipitated opioid withdrawal in nontolerant dogs was associated with dramatic cardiovascular changes and abrupt elevation of serum catecholamine concentrations.^{121,122} The effects were more dramatic in dogs with an elevated PCO₂ than in those with a normal or low PCO₂, suggesting the potential benefit of adequately ventilating patients before opioid reversal with naloxone. Similar effects occur in humans undergoing ultrarapid opioid detoxification (UROD; see later discussion).⁴⁹

Even though abrupt precipitation of withdrawal by naloxone may contribute to the development of ARDS, it cannot be the sole etiology. Alveolar filling was noted in 50% to 90% of the postmortem examinations performed on heroin overdose patients, many of whom were declared dead before arrival to medical care and thus never received naloxone.^{71,75} In addition, neither naloxone nor any other opioid antagonist was available when Osler and others described their initial cases of "pulmonary edema." Alternatively, the negative intrathoracic pressure generated by attempted inspiration against a closed glottis creates a large pressure gradient across the alveolar membrane and draws fluid into the alveolar space. This mechanical effect, also known as the Müller maneuver, was invoked as the cause of ventilator-associated ARDS before the advent of demand ventilators and neuromuscular blockers. In the setting of opioid poisoning, glottic laxity may prevent adequate air entry during inspiration. This effect may be especially prominent at the time of naloxone administration, in which case breathing may be reinstituted before the return of adequate upper airway function.

Cardiovascular. Arteriolar and venous dilation secondary to opioid use may result in a mild reduction in blood pressure.¹⁹⁰ This effect is clinically useful for treatment of patients with acute cardiogenic pulmonary edema. However, although patients typically do not develop significant supine hypotension, orthostatic changes in blood pressure and pulse routinely occur. A reduction in heart rate is common as a result of the associated reduction in CNS stimulation. Opioid induced hypotension appears to be mediated by histamine release, although induction of histamine release does not appear to occur through interaction with an opioid receptor. It may be related to the nonspecific ability of certain xenobiotics to activate mast cell G-proteins,⁷ which induce degranulation of histamine containing vesicles. Many opioids share this ability, which seems to be conferred by the presence of a positive charge on a hydrophobic molecule. Accordingly, not all opioids are equivalent in their ability to release histamine.⁷ After administration of one of four different opioids to 60 healthy patients, meperidine produced the most hypotension and elevation of serum histamine concentrations; fentanyl produced the least.⁵³ The combination of H₁ and H₂ antagonists is effective in ameliorating the hemodynamic effects of

opioids in humans.¹³⁵

Adulterants or coingestants may produce significant cardiovascular toxicity. For example, quinine adulterated heroin is associated with dysrhythmias. Cocaine, surreptitiously added to heroin, may cause significant myocardial ischemia or infarction. Similarly, concern that naloxone administration may “unmask” cocaine toxicity in patients simultaneously using cocaine and heroin (“speedball”) probably is warranted but rarely is demonstrated unequivocally.

Certain opioids at therapeutic concentrations, particularly methadone, may interfere with normal cardiac repolarization and produce QT interval prolongation, an effect that predisposes to the development of torsade de pointes.^{99,127} Many patients who receive methadone experience minor increases in QT interval, although a small percentage of patients experience a substantial increase to more than 500 msec.⁹⁹ Methadone and levo- α -acetylmethadol (LAAM) both prolong the QT interval via interactions with cardiac K⁺ channels.⁹³ Additionally, certain opioids, primarily propoxyphene (which was recently removed from the US market), may alter the function of myocardial Na⁺ channels in a manner similar to that of the antidysrhythmics (Chap. 64).

Miosis. Stimulation of parasympathetic pupilloconstrictor neurons in the Edinger-Westphal nucleus of the oculomotor nerve by morphine produces miosis. Additionally, morphine increases firing of pupilloconstrictor neurons to light,¹⁰⁶ which increases the sensitivity of the light reflex through central reinforcement.¹⁹³ Although sectioning of the optic nerve may blunt morphine-induced miosis, the consensual reflex in the denervated eye is enhanced by morphine. Because opioids classically mediate inhibitory neurotransmission, hyperpolarization of sympathetic nerves or of inhibitory neurons to the parasympathetic neurons (removal of inhibition) ultimately may be found to mediate the classic “pinpoint pupil” associated with opioid use.

Not all patients using opioids present with miosis. Meperidine has a lesser miotic effect than other conventional opioids, and propoxyphene use does not result in miosis.⁵⁹ Use of opioids with predominantly δ -agonist effects, such as pentazocine, may not result in miosis. Mydriasis may occur in severely poisoned patients secondary to hypoxic brain insult. Additionally, concomitant drug abuse or the presence of adulterants may alter pupillary findings. For example, the combination of heroin and cocaine (“speedball”) may produce virtually any size pupil, depending on the relative contribution by each xenobiotic. Similarly, patients ingesting diphenoxylate and atropine (Lomotil) or those using scopolamine adulterated heroin typically develop mydriasis.⁶⁸

Seizures. Seizures are a rare complication of therapeutic use of most opioids. In patients with acute opioid overdose, seizures most likely are caused by hypoxia. However, experimental models demonstrate a proconvulsant effect of morphine in that it potentiates the convulsant effect of other xenobiotics.¹⁹⁸ These effects are variably inhibited by naloxone, suggesting the involvement of a mechanism other than opioid receptor binding. In humans, morphine-induced seizures are reported in neonates and are reversed by naloxone,³⁴ although opioid withdrawal seizures in neonates are more common.

Seizures should be anticipated in patients with meperidine, propoxyphene, tapentadol, or tramadol toxicity. Naloxone antagonizes the convulsant effects of propoxyphene in mice, although it is only moderately effective in preventing seizures resulting from meperidine or its metabolite normeperidine.⁶⁰ Interestingly, naloxone potentiates the anticonvulsant effects of benzodiazepines and barbiturates, but in a single study, it antagonized the effects of phenytoin.⁸⁵ The ability of fentanyl and its analogs to induce seizures is controversial. They are used to activate epileptiform activity for localization in patients with temporal lobe epilepsy who are undergoing surgical exploration.¹¹⁷ However, electroencephalography (EEG) performed on patients undergoing fentanyl anesthesia did not identify seizure activity even though the clinical assessment suggested that approximately one-third of them had seizures.¹⁶⁴ It appears likely that the rigidity and myoclonus associated with fentanyl use are readily misinterpreted as a seizure.

Movement Disorders. Patients may experience acute muscular rigidity with rapid IV injection of certain high potency opioids, especially fentanyl and its derivatives.¹⁷³ This condition is particularly prominent during induction of anesthesia and in neonates.⁵² The rigidity primarily involves the trunk and may impair chest wall movement sufficiently to exacerbate hypoventilation. Chest wall rigidity may have contributed to the lethality associated with epidemics of fentanyl adulterated or fentanyl substituted heroin. Although the mechanism of muscle rigidity is unclear, it may be related to blockade of dopamine receptors in the basal ganglia. Other postulated mechanisms include γ -aminobutyric acid (GABA) antagonism and NMDA agonism. Opioid antagonists generally are therapeutic but may produce adverse hemodynamic effects, withdrawal phenomena, or uncontrollable pain, depending on the situation.⁵² Although not a problem for patients taking stable doses of methadone, rapid escalation of methadone doses may produce choreoathetoid movements.¹¹

Gastrointestinal Effects. Historically, the morphine analog apomorphine was used as a rapidly acting emetic whose clinical use was limited by its tendency to depress the patient’s level of consciousness. Emesis induced by apomorphine is mediated through agonism at D₂ receptor subtypes within the chemoreceptor trigger zone of the medulla. Many opioids, particularly morphine, produce significant nausea and vomiting when used therapeutically.²³ Whether these effects are inhibited by naloxone is not clearly established, but they likely are not.

Although diphenoxylate and loperamide are widely used therapeutically to manage diarrhea, opioid-induced constipation is most frequently a bothersome side effect of both medical and nonmedical use of opioids. Constipation,

mediated by μ_2 receptors within the smooth muscle of the intestinal wall,⁸⁰ is ameliorated by oral naloxone. Provided the first pass hepatic glucuronidative capacity is not exceeded (at doses of ~6 mg), enteral naloxone is poorly bioavailable and thus induces few, if any, opioid withdrawal symptoms.¹¹⁹ Methylnaltrexone and alvimopan are bioavailable, “peripherally restricted” opioids that cannot cross the blood brain barrier. Although they antagonize the effects of opioids on the GI tract opioid receptor,^{17,200} opioid withdrawal does not occur¹¹⁸ (Antidotes in Depth: A4).

Endocrine Effects. Chronic use of opioids is associated with hypofunction of the hypothalamic pituitary gonadal axis by binding to hypothalamic opioid receptors and decreasing the secretion of gonadotropin releasing hormone.¹⁵ Clinical findings include reduced libido, erectile dysfunction, hot flashes, and depression, as well as anemia, hair loss, and osteopenia.¹⁵⁴ Additionally, both men and women may have infertility. Furthermore, opioids reduce the release of corticotropin-releasing hormone from the hypothalamus, leading to a reduction of adrenocorticotrophic hormone (ACTH) release from the pituitary. This reduces adrenal function, and clinically relevant adrenal insufficiency may occur.¹⁵ In addition, prolactin concentrations commonly rise and may lead to gynecomastia.¹⁴⁰

Hearing Loss. Although relatively rare, rapidly progressive sensorineural hearing loss may occur in heavy users of opioid analgesics.⁷⁷ This effect has been associated with most opioids, including hydrocodone, oxycodone, and methadone. The mechanism remains unknown, and suggested causes include ischemia, genetic predisposition, direct cochlear toxicity, and hypersensitization that manifests upon re-exposure after a period of opioid abstinence.¹⁵⁷ Most patients recover after abstinence, although some are only successfully treated with cochlear implants (Chap. 26).⁷⁷

DIAGNOSTIC TESTING

Laboratory Considerations

Opioid-poisoned patients are particularly appropriate for a rapid clinical diagnosis because of the unique characteristics of the opioid toxic syndrome. Additionally, even in situations in which the assay results are available rapidly, the fact that several distinct classes of opioids and nonopioids can produce similar opioid effects limits the use of laboratory tests, such as immunoassays, that rely on structural features to identify xenobiotics. Furthermore, because opioids may be chemically detectable long after their clinical effects have dissipated, assay results cannot be considered in isolation but rather viewed in the clinical context. Several well-described problems with laboratory testing of opioids are described here and in Chap. 6.

Cross-Reactivity. Many opioids share significant structural similarities, such as morphine and oxycodone or methadone and propoxyphene, but they do not necessarily share the same clinical characteristics (Fig. 38–2). Because most clinical assays depend on structural features for identification, structurally similar xenobiotics may be detected in lieu of the desired one. Whether a similar xenobiotic is noted by the assay depends on the sensitivity and specificity of the assay and the serum concentration of the xenobiotic. Some cross-reactivities are predictable, such as that of oxycodone with morphine, on a variety of screening tests. Other cross-reactivities are less predictable, as in the case of the cross-reaction of dextromethorphan and the phencyclidine (PCP) component of the fluorescence polarization immunoassay (Abbott TDx),¹⁵⁰ a widely used drug abuse screening test (Chap. 6).¹⁷⁰

FIGURE 38–2. The figure demonstrates the structural similarities between methadone and propoxyphene and between phencyclidine and dextromethorphan.

Congeners and Adulterants. Commercial opioid assays, which are specific for morphine, will not readily detect most of the semisynthetic and synthetic opioids. In some cases, epidemic fatalities involving fentanyl derivatives remained unexplained despite obvious opioid toxicity until the ultrapotent fentanyl derivative α -methylfentanyl (although initially misidentified as 3-methylfentanyl) was identified by more sophisticated testing.^{98,113} Oxycodone, hydrocodone, and other common morphine derivatives have variable detectability by different opioid screens and generally only when in high concentrations.¹¹⁰

Drug Metabolism. A fascinating dilemma may arise in patients who ingest moderate to large amounts of poppy seeds.⁹⁶ These seeds, which are widely used for culinary purposes, are derived from poppy plants and contain both morphine and codeine. After ingestion of a single poppy seed bagel, patients may develop elevated serum morphine and codeine concentrations and test positive for morphine.^{124,144} Because the presence of morphine on a drug abuse screen may suggest illicit heroin use, the implications are substantial. Federal workplace testing regulations thus require corroboration of a positive morphine assay with assessment of another heroin metabolite, 6-monoacetylmorphine, before reporting a positive result.^{125,184} Humans cannot acetylate morphine and therefore cannot synthesize 6-monoacetylmorphine, but humans can readily deacetylate heroin, which is diacetylmorphine.

A similar problem may occur in patients taking therapeutic doses of codeine. Because codeine is demethylated to morphine by CYP2D6, a morphine screen may be positive as a result of metabolism and not structural cross-reactivity.⁵⁶ Thus, determination of the serum codeine or 6-monoacetylmorphine concentration is necessary in these patients.

Determination of the serum codeine concentration is not foolproof, however, because codeine is present in the opium preparation used to synthesize heroin.

Forensic Testing. Decision making regarding the cause of death in the presence of systemic opioids often is complex.³⁶ Variables that often are incompletely defined contribute substantially to the difficulty in attributing or not attributing the cause of death to the opioid. These variables include the specifics regarding the timing of exposure, the preexisting degree of sensitivity or tolerance, the role of cointoxicants (including parent opioid metabolites), and postmortem redistribution and metabolism.^{44,92} Interesting techniques to help further elucidate the likely cause of death that have been studied include the application of postmortem pharmacogenetic principles⁸⁶ and the use of alternative specimens ([Chap. 34](#)).

MANAGEMENT

The consequential effects of acute opioid poisoning are CNS and respiratory depression. Although early support of ventilation and oxygenation is generally sufficient to prevent death, prolonged use of bag-valve-mask ventilation and endotracheal intubation may be avoided by cautious administration of an opioid antagonist. Opioid antagonists, such as naloxone, competitively inhibit binding of opioid agonists to opioid receptors, allowing the patient to resume spontaneous respiration. Naloxone competes at all receptor subtypes, although not equally, and is effective at reversing almost all adverse effects mediated through opioid receptors (Antidotes in Depth: A4).

Because many clinical findings associated with opioid poisoning are nonspecific, the diagnosis requires clinical acumen. Differentiating acute opioid poisoning from other etiologies with similar clinical presentations may be challenging. Patients manifesting opioid toxicity, those found in an appropriate environment, or those with characteristic physical clues such as fresh needle marks require little corroborating evidence. However, subtle presentations of opioid poisoning may be encountered, and other entities superficially resembling opioid poisoning may occur. Hypoglycemia, hypoxia, and hypothermia may result in clinical manifestations that share features with opioid poisoning and may exist concomitantly. Each can be rapidly diagnosed with routinely available, point-of-care testing, but their existence does not exclude opioid toxicity. Other xenobiotics responsible for similar clinical presentations include clonidine, PCP, phenothiazines, and sedative-hypnotics (primarily benzodiazepines). In such patients, clinical evidence usually is available to assist in diagnosis. For example, nystagmus nearly always is noted in PCP toxic patients, hypotension or electrocardiographic (ECG) abnormalities in phenothiazine-poisoned patients, and coma with virtually normal vital signs in patients poisoned by benzodiazepines. Most difficult to differentiate on clinical grounds may be toxicity produced by the centrally acting antihypertensive agents such as clonidine (see Clonidine later and [Chap. 63](#)). Additionally, myriad traumatic, metabolic, and infectious etiologies may occur simultaneously and must always be considered and evaluated appropriately.

Antidote Administration

The goal of naloxone therapy is not necessarily complete arousal; rather, the goal is reinstitution of adequate spontaneous ventilation. Because precipitation of withdrawal is potentially detrimental and often unpredictable, the lowest practical naloxone dose should be administered initially, with rapid escalation as warranted by the clinical situation. Most patients respond to 0.04 to 0.05 mg of naloxone administered IV, although the requirement for ventilatory assistance may be slightly prolonged because the onset may be slower than with larger doses. Administration in this fashion effectively avoids endotracheal intubation and allows timely identification of patients with nonopioid causes of their clinical condition yet diminishes the risk of precipitation of acute opioid withdrawal. SC administration may allow for smoother arousal than the high-dose IV route but is unpredictable in onset and likely prolonged in offset.¹⁸⁸ Prolonged effectiveness of naloxone by the SC route can be a considerable disadvantage if the therapeutic goal is exceeded and the withdrawal syndrome develops.

In the absence of a confirmatory history or diagnostic clinical findings, the cautious empiric administration of naloxone may be both diagnostic and therapeutic. Naloxone, even at extremely high doses, has an excellent safety profile in opioid-naïve patients receiving the medication for nonopioid-related indications, such as spinal cord injury or acute ischemic stroke. However, administration of naloxone to opioid-dependent patients may result in adverse effects; specifically, precipitation of an acute withdrawal syndrome should be anticipated. The resultant agitation, hypertension, and tachycardia may produce significant distress for the patient and complicate management for the clinical staff and occasionally may be life threatening. Additionally, emesis, a common feature of acute opioid withdrawal, may be particularly hazardous in patients who do not rapidly regain consciousness after naloxone administration. For example, patients with concomitant ethanol or sedative-hypnotic exposure and those with head trauma are at substantial risk for pulmonary aspiration of vomitus if their airways are unprotected.

Identification of patients likely to respond to naloxone conceivably would reduce the unnecessary and potentially dangerous precipitation of withdrawal in opioid-dependent patients. Routine prehospital administration of naloxone to all patients with subjectively assessed altered mental status or respiratory depression was not beneficial in 92% of patients.¹⁹⁹ Alternatively, although not perfectly sensitive, a respiratory rate of 12 breaths/min or less in an unconscious patient

presenting via emergency medical services best predicted a response to naloxone.⁷⁸ Interestingly, neither respiratory rate below 8 breaths/min nor coma was able to predict a response to naloxone in hospitalized patients.¹⁹⁵ It is unclear whether the discrepancy between the latter two studies is a result of the demographics of the patient groups or whether patients with prehospital opioid overdose present differently than patients with iatrogenic poisoning. Regardless, relying on the respiratory rate to assess the need for ventilatory support or naloxone administration is not ideal because hypoventilation secondary to hypopnea may precede that caused by bradypnea.^{142,161}

The decision to discharge a patient who awakens appropriately after naloxone administration is based on practical considerations. Patients presenting with profound hypoventilation or hypoxia are at risk for development of ARDS or posthypoxic encephalopathy. Thus, it seems prudent to observe these patients for at least 24 hours in a medical setting. Patients manifesting only moderate signs of poisoning who remain normal for at least several hours after parenteral naloxone likely are safe to discharge. However, the need for psychosocial intervention in patients with uncontrolled drug use or after a suicide attempt may prevent discharge from the emergency department (ED).

Patients with recurrent or profound poisoning by long acting opioids, such as methadone, or patients with large GI burdens (eg, “body packers” or those taking sustained release preparations) may require continuous infusion of naloxone to ensure continued adequate ventilation (Table 38–3). An hourly infusion rate of two thirds of the initial reversal dose of naloxone is sufficient to prevent recurrence.⁶² Titration of the dose may be necessary as indicated by the clinical situation. Although repetitive bolus dosing of naloxone may be effective, it is labor intensive and subject to error.

TABLE 38–3. How to Use Naloxone

1. If a naloxone bolus (start with 0.04 mg IV and titrate) is successful, administer two-thirds of the effective bolus dose per hour by IV infusion; frequently reassess the patient’s respiratory status.
2. If respiratory depression is not reversed after the initial bolus dose: Administer up to 10 mg of naloxone as an IV bolus. If the patient does not respond, do not initiate an infusion.

OR

Intubate the patient, as clinically indicated.

3. If the patient develops withdrawal after the bolus dose: Allow the effects of the bolus to abate. If respiratory depression recurs, administer half of the initial bolus dose and begin an IV infusion at two-thirds of the new bolus dose per hour. Frequently reassess the patient’s respiratory status.
4. If the patient develops withdrawal signs or symptoms during the infusion: Stop the infusion until the withdrawal symptoms abate. Restart the infusion at half the initial rate; frequently reassess the patient’s respiratory status. Exclude withdrawal from other xenobiotics.
5. If the patient develops respiratory depression during the infusion: Readminister half of the initial bolus and repeat until reversal occurs. Increase the infusion by half of the initial rate; frequently reassess the patient’s respiratory status. Exclude continued absorption, readministration of opioid, and other etiologies as the cause of the respiratory depression.

IV = intravenous.

Despite the availability of long-acting opioid antagonists (eg, naltrexone) that theoretically permit single-dose reversal of methadone poisoning, the attendant risk of precipitating an unrelenting withdrawal syndrome hinders their use as antidotes for initial opioid reversal. However, these long acting opioid antagonists may have a clinical role in the maintenance of consciousness and ventilation in opioid-poisoned patients already awakened by naloxone. Prolonged observation and perhaps antidote readministration may be required to match the pharmacokinetic parameters of the two antagonists. Otherwise well children who ingest short-acting opioids may be given a long-acting opioid antagonist initially because they are not expected to develop a prolonged, potentially hazardous withdrawal. However, the same caveats remain regarding the need for extended hospital observation periods if ingestion of methadone or other long-acting opioids is suspected.

Rapid and Ultrarapid Opioid Detoxification

The concept of antagonist-precipitated opioid withdrawal is promoted extensively as a “cure” for opioid dependency, particularly heroin and oxycodone, but has fallen out of favor in recent years. Rather than slow, deliberate withdrawal or detoxification from opioids over several weeks, antagonist-precipitated withdrawal occurs over several hours or days.⁶⁵ The purported advantage of this technique is a reduced risk of relapse to opioid use because the duration of discomfort is reduced and a more rapid transition to naltrexone maintenance can be achieved. Although most studies find some beneficial short-term results, relapse to drug use is very common.¹¹⁶ Rapid opioid detoxification techniques are usually offered by outpatient clinics and typically consist of naloxone- or naltrexone-precipitated opioid withdrawal tempered with varying

amounts of clonidine, benzodiazepines, antiemetics, or other drugs. UROD uses a similar concept but involves the use of deep sedation or general anesthesia for greater patient control and comfort. The risks of these techniques are not fully defined but are of substantial concern. Massive catecholamine release, ARDS, kidney injury, and thyroid hormone suppression have been reported after UROD, and many patients still manifest opioid withdrawal 48 hours after the procedure. As with other forms of opioid detoxification, the loss of tolerance after successful completion of the program paradoxically increases the likelihood of death from heroin overdose if these individuals relapse. That is, recrudescence of opioid use in predetoxification quantities is likely to result in overdose.¹⁷² Both techniques are costly; UROD under anesthesia commonly costs thousands of dollars. Professional medical organizations involved in addiction management have publicly expressed concern for this form of detoxification.²

SPECIFIC OPIOIDS

The vast majority of opioid-poisoned patients follow predictable clinical courses that can be anticipated based on our understanding of opioid receptor pharmacology. However, certain opioids taken in overdose may produce atypical manifestations. Therefore, careful clinical assessment and institution of empiric therapy usually are necessary to ensure proper management (Table 38–4).

TABLE 38–4. Classification, Potency, and Characteristics of Opioids and Opioid Antagonists

Opioid (Representative Trade Name)	Type ^a	Derivation	Analgesic Dose (mg) (via route, equivalent to 10 mg of morphine SC ^b)	Comments ^{c,d}
Alvimopan (Entereg)	Ant	Synthetic	Nonanalgesic (12 PO)	Peripherally acting antagonist; reverses opioid constipation
Buprenorphine (Suboxone)	PA	Semisynthetic	0.4 IM	Opioid substitution therapy requires 6–16 mg/day (contains naloxone)
Butorphanol (Stadol)	AA	Semisynthetic	2 IM	
Codeine	Ag	Natural	120 PO	Often combined with acetaminophen; requires demethylation to morphine by CYP2D6
Dextromethorphan (Robitussin DM)	NEC	Semisynthetic	Nonanalgesic (10–30 PO)	Antitussive; psychotomimetic via NMDA receptor
Difenoxylate (Lomotil)	Ag	Synthetic	Nonanalgesic (2.5 PO)	Antidiarrheal, combined with atropine; difenoxin is potent metabolite
Fentanyl (Sublimaze)	Ag	Synthetic	0.125 IM	Very short acting (<1 hour)
Heroin (Diamorph)	Ag	Semisynthetic	5 SC	Diacetylmorphine, used therapeutically in some countries; schedule I medication in the United States
Hydrocodone (Vicodin, Hycodan)	Ag	Semisynthetic	10 PO	
Hydromorphone (Dilaudid)	Ag	Semisynthetic	1.3 SC	
LAAM (Orlaam)	Ag	Synthetic	(Flexible oral dosing ^e)	Long acting, potent metabolites; no longer distributed in United States because of QT interval prolongation
Levorphanol (Levodromoran)	Ag	Semisynthetic	2 SC/IM	
Loperamide (Imodium)	Ag	Synthetic	Nonanalgesic (2 PO)	Antidiarrheal
Meperidine, pethidine (Demerol)	Ag	Synthetic	75 SC/IM	Seizures caused by metabolite accumulation
Methadone (Dolophine)	Ag	Synthetic	10 IM	Very long acting (24 hours)
Methylnaltrexone (Relistor)	Ant	Synthetic	Nonanalgesic (8–12 SC)	Peripherally acting antagonist; reverses opioid induced constipation
Morphine	Ag	Natural	10 SC/IM	
Nalbuphine (Nubain)	AA	Semisynthetic	10 IM	
Nalorphine	AA	Semisynthetic	15 IM	Historically used as an opioid antagonist ^f
Naloxone (Narcan)	Ant	Semisynthetic	Nonanalgesic (0.04 IV/IM)	Short-acting antagonist (0.5 hours)
Naltrexone (Trexan, Revia)	Ant	Semisynthetic	Nonanalgesic (50 PO)	Very long-acting antagonist (24 hours)
Oxycodone (Percocet, OxyContin)	Ag	Semisynthetic	10 PO	Often combined with acetaminophen; OxyContin is sustained release
Oxymorphone (Numorphan, Opuna)	Ag	Semisynthetic	1 SC	
Paragoric (Parapectolin)	Ag	Natural	25 mL PO	Tincture of opium (0.4 mg/mL)
Pentazocine (Talwin)	AA	Semisynthetic	50 SC	Psychotomimetic via receptor
Propoxyphene (Darvon)	Ag	Synthetic	65 PO	Seizures, dysrhythmias
Tapentadol (Nucynta)	Ag	Synthetic	50–100 PO	Seizures
Tramadol (Ultram)	Ag	Synthetic	50–100 PO	Seizures possible with therapeutic dosing

^aAgonist-antagonists, partial agonists, and antagonists may cause withdrawal in tolerant individuals. ^bTypical dose (mg) for analgesics without analgesic effects is given in parentheses. ^cDuration of therapeutic clinical effect 3–4 hours unless noted, likely to be exaggerated in overdose. ^dAlthough approximately equivalent with methadone, LAAM is not used as an analgesic.

AA = agonist-antagonist (α-agonist, β-antagonist); Ag = full agonist (μ, κ, δ); Ant = full antagonist (μ, κ, δ-antagonist); IM = intramuscular; IV = intravenous; NEC = not easily classified; NMDA = N-methyl-D-aspartate; PA = partial agonist (μ, κ, agonist, α-antagonist); PO = oral; SC = subcutaneous.

Morphine and Codeine

Morphine is poorly bioavailable by the oral route because of extensive first-pass elimination. Morphine is hepatically metabolized primarily to morphine-3-glucuronide (M3G) and, to a lesser extent, to morphine-6-glucuronide (M6G), both of which are cleared renally. Unlike M3G, which is essentially devoid of activity, M6G has μ -agonist effects in the CNS.²³ However, M6G administered peripherally is significantly less potent as an analgesic than is morphine.¹⁶⁰ The polar glucuronide has a limited ability to cross the blood–brain barrier, and P-glycoprotein is capable of expelling M6G from the cerebrospinal fluid. The relative potency of morphine and M6G in the brain is incompletely defined, but the metabolite is generally considered to be several-fold more potent.³

Codeine itself is an inactive opioid agonist, and it requires metabolic activation by O-demethylation to morphine by CYP2D6 (Fig. 38–3). This typically represents a minor metabolic pathway for codeine metabolism. N-Demethylation into norcodeine by CYP3A4 and glucuronidation are more prevalent but produce inactive metabolites. The need for conversion to morphine explains why approximately 5% to 7% of white patients, who are devoid of CYP2D6 function, cannot derive an analgesic response from codeine.^{83,101} An increasingly recognized phenomenon is that ultrarapid CYP2D6 metabolizers produce unexpectedly large amounts of morphine from codeine, with resulting life-threatening opioid toxicity.^{55,138}

FIGURE 38–3. Opiate and opioid metabolism. Codeine can be O-methylated to morphine, N-demethylated to norcodeine, or glucuronidated to codeine-6-glucuronide (codeine-6-G). Morphine can be N-demethylated to normorphine or glucuronidated to either morphine-3-glucuronide (morphine-3-G) or morphine-6-glucuronide (morphine-6-G). Heroin is converted to morphine by a two-step process involving plasma cholinesterase and two human liver carboxylesterases known as human carboxylesterase-1 and human carboxylesterase-2.

Heroin

Heroin is 3,6-diacetylmorphine, and its exogenous synthesis is performed relatively easily from morphine and acetic anhydride. Heroin has a lower affinity for the receptor than does morphine, but it is rapidly metabolized by plasma

cholinesterase and liver human carboxylesterase (hCE)-2 to 6-monoacetylmorphine, a more potent μ agonist than morphine (Fig. 38–3).¹⁵⁵ Users claim that heroin has an enhanced euphorogenic effect, often described as a “rush.” This effect likely is related to the enhanced blood–brain barrier penetration occasioned by the additional organic functional groups of heroin and its subsequent metabolic activation within the CNS. Interestingly, cocaine and heroin compete for metabolism by plasma cholinesterase and the two human liver carboxylesterases hCE-1 and hCE-2. This interaction may have pharmacokinetic and clinical consequences in patients who “speedball.”^{9,90}

Heroin can be obtained in two distinct chemical forms: base or salt. The hydrochloride salt form typically is a white or beige powder and was the common form of heroin available before the 1980s.⁸⁸ Its high water solubility allows simple IV administration. Heroin base, on the other hand, now is the more prevalent form of heroin in most regions of the world. It often is brown or black. “Black tar heroin” is one appellation referring to an impure South American import available in the United States. Because heroin base is virtually insoluble in water, IV administration requires either heating the heroin until it liquefies or mixing it with acid. Alternatively, because the alkaloidal form is heat stable, smoking or “chasing the dragon” is sometimes used as an alternative route. Street-level heroin base frequently contains caffeine or barbiturates,⁸⁸ which improves the sublimation of heroin and enhances the yield.⁸¹

Widespread IV use has led to many significant direct and indirect medical complications, particularly endocarditis and AIDS, in addition to fatal and nonfatal overdose. Nearly two-thirds of all long-term (>10 years) heroin users in Australia had overdosed on heroin.⁴⁰ Among recent-onset heroin users, 23% had overdosed on heroin, and 48% had been present when someone else overdosed.⁶³ Risk factors for fatality after heroin use include the concomitant use of other drugs of abuse, particularly ethanol; recent abstinence, as occurs during incarceration¹⁵³; and perhaps unanticipated fluctuations in the purity of available heroin.^{37,143} Because most overdoses occur in seasoned heroin users and about half occur in the company of other users,⁴⁰ the prescribing of naloxone to heroin users for companion administration has become increasingly available but remains poorly studied.²⁰ Although earlier administration of antidote could be beneficial, certain issues make this approach controversial. For example, despite the acknowledged injection skills of the other users in the “shooting gallery,” their judgment likely is impaired. In one survey, summoning an ambulance was the initial response to overdose of a companion in only 14% of cases.³⁹ A survey of heroin users suggested they lacked an understanding of the pharmacology of naloxone, which might lead to inappropriate behaviors regarding both heroin and naloxone administration.¹⁵²

Recognition of the efficacy of intranasal heroin administration, or snorting, has fostered a resurgence of heroin use, particularly in suburban communities. The reasons for this trend are unclear, although it is widely suggested that the increasing purity of the available heroin has rendered it more suitable for intranasal use. However, because intranasal administration of a mixture of 3% heroin in lactose produces clinical and pharmacokinetic effects similar to an equivalent dose administered IM, the relationship between heroin purity and price and intranasal use is uncertain.^{28,146} Needle avoidance certainly is important, reducing the risk of transmission of various infectious diseases, including HIV. Heroin smoking has also increased in popularity in the United States, albeit not to the extent in other countries (see Chasing the Dragon later). In addition, users of prescription drugs such as oxycodone or hydrocodone may change to heroin as the supplies of prescription opioids tighten and prices rise.⁸⁷ Celebrities and blogs have popularized intranasal heroin use as a “safe” alternative to IV use. This usage is occurring despite a concomitantly reported rise in heroin deaths in regions of the country where its use is prevalent. Although intranasal use may be less dangerous than IV use from an infectious disease perspective, it is clear that both fatal overdose and drug dependency remain common.¹⁷⁸

Adulterants, Contaminants, and “Heroin” Substitutes. The history of heroin adulteration and contamination has been extensively described. Retail (street-level) heroin almost always contains adulterants or contaminants. What differentiates the two is the intent of their admixture. Adulterants typically are benign because inflicting harm on the consumer with their addition would be economically and socially unwise, although adulterants occasionally are responsible for epidemic deaths. Interestingly, most heroin overdose fatalities do not have serum morphine concentrations that substantially differ from those of living users, raising the unlikely possibility that the individual death is related to an adulterant or contaminant.³⁸

Historically, alkaloids, such as quinine and strychnine, were used to adulterate heroin to mimic the bitter taste of heroin and to mislead clients. Quinine may have first been added in a poorly reasoned attempt to quell an epidemic of malaria among IV heroin users in New York City in the 1930s.⁷¹ That quinine adulteration was common is demonstrated by the common practice of urine screening for quinine as a surrogate marker for heroin use. However, quinine was implicated as a causative factor in an epidemic of heroin-related deaths in the District of Columbia between 1979 and 1982. Toxicity attributed to quinine in heroin users includes cardiac dysrhythmias (Chap. 16), amblyopia, and thrombocytopenia. Quinine adulteration currently is much less common than it was in the past. Trend analysis of illicit wholesale and street-level heroin adulteration over a 12-year period in Denmark revealed that although caffeine, acetaminophen (APAP), methaqualone, and phenobarbital all were prevalent adulterants, quinine was not found.⁸⁸ Recent data on adulteration in the United States are unavailable. Many other adulterants or contaminants, including thallium, lead, cocaine, and amphetamines, are reported.

Poisoning by scopolamine-tainted heroin reached epidemic levels in the northeastern United States in 1995.⁶⁸ Exposed patients presented with acute psychosis and anticholinergic signs. Several patients were treated with physostigmine, with excellent therapeutic results.

Clenbuterol, a β_2 -adrenergic agonist with a rapid onset and long duration of action, was found to be a contaminant in street heroin in the Eastern United States in early 2005. Users rapidly developed nausea, chest pain, palpitations, dyspnea, and tremor. Physical findings included significant tachycardia and hypotension, as well as hyperglycemia, hypokalemia, and increased lactate concentrations on laboratory evaluation, and a few fatalities occurred.^{79,197} The initial patients were thought to be cyanide poisoned. Several patients were treated with β -adrenergic antagonists or calcium channel blockers and potassium supplementation with good results.

“Chasing the Dragon.” IV injection and insufflation are the preferred means of heroin self-administration in the United States. In other countries, including the Netherlands, the United Kingdom, and Spain, a prevalent method is “chasing the dragon” whereby users inhale the white pyrolysate that is generated by heating heroin base on aluminum foil using a handheld flame. This means of administration produces heroin pharmacokinetics similar to those observed after IV administration.⁷³ Chasing the dragon is not a new phenomenon, but it has gained acceptance recently among both IV heroin users and drug-naïve individuals. The reasons for this shift are diverse but probably are related to the avoidance of injection drug use with its concomitant infectious risks.

In the early 1980s, a group of individuals who smoked and inhaled heroin in the Netherlands developed spongiform leukoencephalopathy. Other causes of this rare clinicopathologic entity include prion-related infections such as bovine spongiform leukoencephalopathy, hexachlorophene, pentachlorophenol, and metal poisoning, although none appeared responsible for this phenomenon. Since the initial report, similar cases have been reported in other parts of Europe and in the United States.^{100,109} Initial findings may occur within 2 weeks of use and include bradykinesia, ataxia, abulia, and speech abnormalities. Of those whose symptoms do not progress, half may recover. However, in others, progression to spastic paraparesis, pseudobulbar palsy, or hypotonia may occur over several weeks. Approximately half of individuals in this group do not develop further deficits or improve, but death occurs in approximately 25% of reported cases. The prominent symmetric cerebellar and cerebral white matter destruction noted on brain computed tomography and magnetic resonance imaging corresponds to that noted at necropsy.^{95,129}

The syndrome has the characteristics of a point-source toxic exposure, but no culpable contaminants have been identified, although aluminum concentrations may be elevated.⁵¹ A component or pyrolysis product unique to certain batches of “heroin” is possible.¹⁶ Treatment is largely supportive. Based on the finding of regional mitochondrial dysfunction on functional brain imaging and an elevated brain lactate concentration, supplementation with 300 mg four times a day of coenzyme Q has purported benefit but has not undergone controlled study.¹⁰⁰

Other Opioids

Fentanyl and Its Analogs. Fentanyl is a short-acting opioid agonist that has approximately 50 to 100 times the potency of morphine. It is well absorbed by the transmucosal route, accounting for its use in the form of a “lozenge.” Fentanyl is widely abused as a heroin substitute (intentionally or because of adulteration) and is the controlled substance most often abused by anesthesiologists.¹²

Transdermal fentanyl in the form of a patch (Duragesic) was approved in 1991 and is widely used by patients with chronic pain syndromes. Fentanyl has adequate solubility in both lipid and water for transdermal delivery (Special Considerations: SC1).⁹⁷ A single patch contains an amount of drug to provide a transdermal gradient sufficient to maintain a steady-state plasma concentration for approximately 3 days (eg, a 50 $\mu\text{g}/\text{h}$ patch contains 5 mg). However, even after the patch is considered exhausted, approximately 50% of the total initial fentanyl dose remains. Interindividual variation in dermal drug penetration and errors in proper use, such as use of excessive patches or warming of the skin, may lead to an iatrogenic fentanyl overdose. Fentanyl patch misuse and abuse occur either by application of one or more patches to the skin or by withdrawal or extraction of the fentanyl from the reservoir for subsequent administration.¹⁷⁷

Regional epidemics of heroin substitutes with “superpotent” activity occasionally produce a dramatic increase in “heroin-related” fatalities. Epidemic deaths among heroin users first appeared in Orange County, California, in 1979 and were traced to α -methylfentanyl sold under the brand name China White.⁹⁸ Similar epidemics of China White poisoning occurred in Pittsburgh in 1988 and in Philadelphia in 1992, although the adulterant in these cases was 3-methylfentanyl, another potent analog. A later epidemic in New York City marked the reappearance of 3-methylfentanyl under the brand name Tango and Cash. Typically, patients present comatose and apneic, with no opioids detected on routine blood and urine analysis. In such cases, unsuspecting users had administered their usual “dose of heroin,” measured in 25-mg “bags” that contained variable amounts of the fentanyl analog. Because of the exceptional potency of this fentanyl analog (as much as 6000 times greater than that of morphine), users rapidly developed apnea.

The largest epidemic of more than 1000 fentanyl-related deaths occurred between 2005 and 2007 primarily in the Philadelphia, Chicago, and Detroit regions because of surreptitiously adulterated or substituted heroin. Fentanyl use was

identified by postmortem urine and blood testing or through analysis of unused drug found on either the decedent or persons with whom the decedent shared drugs. In response to this large epidemic, drug users and others were counseled in overdose prevention and cardiopulmonary resuscitation and provided with “take-home” parenteral or intranasal naloxone.²²

Sufentanil and alfentanil are anesthetic opioids with increased potency compared with fentanyl. In some regions of the country, fentanyl and both licit and illicit fentanyl analogs (eg, 3-methylfentanyl and para-fluorofentanyl) are common drugs of abuse. Experienced heroin users could not easily differentiate fentanyl from heroin, although in one study, heroin was noted to provide a more intense “rush.”¹⁰² Although unconfirmed, the xenobiotic used by Russian authorities to overcome terrorists and subdue a hostage situation in Moscow in October 2002 may have been carfentanil,¹⁹¹ a potent μ -receptor agonist that is commonly used as a positron emission tomography scan radioligand.

Although fentanyl is a more potent opioid agonist than heroin, the dose of naloxone required to reverse respiratory depression appears to be similar to that of other common opioids.¹⁷⁶ This is because the binding affinity (K_d) of fentanyl at the μ opioid receptor is similar to that of both morphine and naloxone.^{107,183} In a typical overdose, the quantity of fentanyl is likely to be equipotent to typical heroin. However, if large quantities of fentanyl are involved in the poisoning, higher than normal doses of naloxone may be required for reversal. Use of other opioids, such as sufentanil and buprenorphine, which have higher affinity for opioid receptors (lower K_d), may lead to the need for larger doses of naloxone to reverse the patient’s respiratory depression¹⁰⁷ (Antidotes in Depth: A4).

Oxycodone and Hydrocodone. Both oxycodone and hydrocodone are sold in fixed combination with APAP (eg, Percocet [oxycodone], Vicodin [hydrocodone]), raising concerns about the complications of APAP hepatotoxicity as the dose of opioid is escalated. Several opioids, including oxycodone and oxymorphone, can be obtained in a controlled-release form that contains a large quantity of opioid intended to be released over many hours. Up until recently, abusers were able to crush the tablet, which destroys the sustained-release matrix and liberates large amounts of insufflatable or injectable opioid. New tamper-resistant formulations, required of most extended release opioids, make physical or chemical release of the opioid difficult limiting this practice.¹⁴⁹ Users can still ingest intact large dose pills. The psychoactive effects of these opioids are similar to each other and to other μ receptor agonists^{196,202} and often are used as a substitute for heroin. Opioid dependence, overdose, and death are common sequelae of oxycodone abuse.

Body Packers. In an attempt to transport illicit drugs from one country to another, “mules,” or body packers, ingest large numbers of multiple-wrapped packages of concentrated cocaine or heroin. When the authorities discover such individuals or when individuals in custody become ill, they may be brought to a hospital for evaluation and management. Although these patients generally are asymptomatic on arrival, they are at risk for delayed, prolonged, or lethal poisoning as a consequence of packet rupture.¹⁸⁰ In the past, determining the country of origin of the current journey was nearly diagnostic of packet content. However, because most of the heroin imported into the United States now originates from South America, which is also the major source of imported cocaine, the discernment from cocaine on this basis is impossible. Given the current greater revenue potential of heroin, the majority of body packers carry heroin.⁶¹ Details of diagnosis and management are discussed in Special Considerations: SC5.

Agonist–Antagonists. The opioid agonists in common clinical use tend to have specific binding affinity toward the μ opioid receptor subtype. The agonist–antagonists differ in that they interact with multiple receptor types and may have different effects at each receptor. Thus, although most opioids typically produce either agonist or antagonist effects, the agonist–antagonists generally have agonist effects at the δ -receptor subtype and antagonistic effects at the μ receptor subtype. Therefore, opioids such as pentazocine (Talwin) may elicit a withdrawal syndrome in a μ -opioid–tolerant individual because of antagonist effects at the μ receptor. This effect forms the basis of the claim offered by many methadone-dependent patients that they are “allergic to Talwin.” However, this same drug may act as an analgesic in nonopioid-using patients through its agonist effects at the δ_1 -receptor subtype. Although the clinical effects of agonist–antagonists after overdose resemble those of the other opioids, including lethal respiratory depression,¹³¹ they are less likely than the full agonists to produce severe morbidity or mortality (see Respiratory Depression above).

Pentazocine. Historically, patients abusing pentazocine (Talwin) administered it with tripeleminamine, a blue capsule, accounting for the appellation “T’s and Blues.” Although this mixture has largely fallen out of favor, pentazocine abuse occurs occasionally. The psychotomimetic effects noted with high doses of pentazocine likely are mediated by δ_2 or perhaps σ receptors. Because pentazocine can be readily dissolved, IV injection was a preferred route for its abuse until the commercial formulation was altered to include 0.5 mg naloxone (Talwin NX), which is not orally bioavailable but fully active parenterally.

Xenobiotics Used in Opioid Substitution Therapy: Methadone and Buprenorphine

Two contrasting approaches to the management of patients with chronic opioid use exist, detoxification and maintenance therapy. Detoxification probably is most appropriate for patients motivated or compelled to discontinue opioid use. It can

be performed either by tapered withdrawal of an opioid agonist or with the assistance of opioid antagonists. Maintenance therapy may include use of a long-acting opioid antagonist, such as naltrexone, to pharmacologically block the effects of additional opioid use. Alternatively, and more commonly, maintenance therapy involves opioid substitution therapy.¹⁹

Methadone. Methadone is a synthetic μ opioid receptor agonist used both for treatment of chronic pain and as a maintenance substitute for opioid dependence. Methadone has been available for the latter use for more than 40 years through methadone maintenance treatment programs (MMTPs).⁴³ In MMTPs, the opioid in use is replaced by methadone, which is legal, oral, and long acting. This opioid allows patients to abstain from activities associated with procurement and administration of the abused opioid and eliminates much of the morbidity and mortality associated with illicit drug use. Although often successful in achieving opioid abstinence, some methadone users continue to use heroin, other opioids, and other xenobiotics.⁹²

Methadone is administered as a chiral mixture of (R,S)-methadone. In humans, methadone metabolism is mediated by several cytochrome P450 (CYP) isozymes, mainly CYP3A4 and CYP2B6, and to a lesser extent CYP2D6. CYP2B6 demonstrates stereoselectivity toward (S)-methadone,⁵⁸ and in vivo data show that CYP2B6 slow metabolizer status is associated with high (S)- but not serum (R)-methadone concentrations.³³ In clinical trials, QT prolongation was exacerbated in individuals who were CYP2B6 slow metabolizers, and this population had higher (S)-methadone concentrations.⁴⁶ (R)-methadone is used in Germany and is both more effective and safer than the chiral mixture or the (S) enantiomer, but it is not available in the United States at the present time.

Methadone predictably produces QT interval prolongation because of blockade of the hERG (human ether-a-gogo related gene) channel. In the human heart, the hERG voltage-gated potassium channel mediates the rapidly activating delayed rectifier current ([Chap. 16](#)). Blocking potassium efflux from the cardiac myocyte prolongs cellular repolarization, prolonging the QT interval. Syncope and sudden death caused by ventricular dysrhythmias (eg, torsade de pointes) are the result. Initially described in case reports of patients on high doses of methadone, clinical trials now reveal that methadone can prolong the QT interval in a concentration-dependent fashion.¹¹² Genetic factors in the metabolism of methadone⁴⁶ and probably baseline QT status at the initiation of methadone therapy may underlie and potentially predict adverse effects. (S)-methadone binding to hERG is greater than twofold than that of (R)-methadone and accounts for the cardiotoxicity.⁸⁴

A major difficulty is identification of individuals who are at risk for life-threatening dysrhythmias from methadone-induced QT interval prolongation. Expert-derived guidelines recommend questioning patients about intrinsic heart disease or dysrhythmias, counseling patients initiating methadone therapy, and obtaining a pretreatment ECG and a follow-up ECG at 30 days and yearly.⁹⁹ Patients who receive methadone doses of greater than 100 mg/day might warrant more frequent ECGs, particularly after dose escalation or change in comorbid disease status.⁹⁹ Although these guidelines are disputed by some and limited data exist on the utility of the ECG as a screening test for persons at risk for torsade de pointes from methadone, given its low cost, easy availability, and minimal invasiveness, the guideline recommendations seem practical and appropriate.⁹¹ Although therapeutic methadone is generally safe, rapid dose escalation during induction of therapy may unintentionally produce toxicity and, rarely, fatal respiratory depression.¹⁹ This adverse effect is generally the result of the combination of variable pharmacokinetics (unpredictable but generally long half-life) and the time lag for the development of tolerance.

After a successful therapeutic response to the administration of naloxone, recurrence should be expected because the duration of effect of naloxone is only approximately 30 to 60 minutes. In many cases, continuous infusion of naloxone or possibly administration of a long-acting opioid antagonist is indicated to maintain adequate ventilation ([Table 38–3](#)).

Unintentional methadone overdose may be related to the manner in which MMTPs dispense the drug. Most patients attending MMTPs are given doses of methadone greater than needed to simply prevent withdrawal and in order to prevent surreptitious heroin or other opioid use.¹⁷¹ Additionally, many MMTPs provide their established patients with sufficient methadone to last through a weekend or holiday without the need to revisit the program. This combination of dose and quantity may allow diversion of portions of the dose without the attendant risk of opioid withdrawal. Furthermore, home storage of this surplus drug in inappropriate containers, such as juice containers or baby bottles,⁶⁹ is a cause of unintentional methadone ingestion by children. Such events can be anticipated because methadone is frequently formulated as a palatable liquid and may not be distributed in child-resistant containers. The primary reason for distribution as a liquid, as opposed to the pill form given to patients with chronic pain syndromes, is to ensure dosing compliance at the MMTP. Unfortunately, death is frequent in children who overdose.¹⁰⁸

Buprenorphine. Because prescription of methadone for maintenance therapy is restricted to federally licensed programs, it is inaccessible and inconvenient for many patients. Buprenorphine was approved in 2000 as a schedule III medication for office-based prescription, administered three times weekly, providing an attractive alternative for patients with substantially broader potential for obtaining outpatient therapy. However, because of the initial limitations on patient volume (subsequently expanded), the requirement for physician certification, and possibly the hesitation on the part of community physicians to welcome patients with substance use problems into their practices, many of the perceived benefits of buprenorphine therapy over methadone have not been realized.

Buprenorphine, a partial μ -opioid agonist, in doses of 8 to 16 mg sublingually, is effective at suppressing both opioid withdrawal symptoms and the covert use of illicit drugs. Buprenorphine, although still abused and misused, has a substantially better safety profile than methadone. That is, buprenorphine overdose is associated with markedly less respiratory depression than full agonists such as methadone, and there is no reported effect on the QT interval.

Buprenorphine competes with the extant opioid for the μ receptor; thus, administration of initial doses of buprenorphine in patients taking methadone for opioid substitution therapy can be complicated by opioid withdrawal, particularly in patients on higher doses of methadone. For this reason, the initial dose of buprenorphine is administered in the presence of a physician and when the patient is in mild withdrawal. Buprenorphine cessation results in a mild withdrawal syndrome and for this reason may prove efficacious in opioid detoxification programs.⁴ After the initial doses of buprenorphine, sublingual film containing both buprenorphine and naloxone (Suboxone) are prescribed to prevent their IV use.

At therapeutic doses, buprenorphine produces nearly complete occupancy of the μ opioid receptors, and its receptor affinity is sufficiently strong that it prevents other opioids from binding.⁶⁶ Interestingly, naloxone may prevent the clinical effects of buprenorphine, but the reversal of respiratory effects by naloxone appears to be related in a nonlinear fashion. Relatively low bolus doses of IV naloxone have no effect on the respiratory depression induced by buprenorphine, but high doses (5–10 mg) caused only partial reversal of the respiratory effects of buprenorphine. More recently, data in healthy volunteers suggest a bell-shaped dose response to naloxone.^{148,181} Although doses that would reverse other opioids were ineffective (0.2–0.4 mg), increasing the dose of naloxone to 2 to 4 mg caused full reversal of buprenorphine respiratory depression. However, the onset of reversal is usually slower than occurs when antagonizing other opioids.¹⁸¹ Further increasing the naloxone dose to 5 to 7 mg caused a decline in reversal activity and actually increased the degree of respiratory depression. The reasons for this are unclear. Therefore, reversal of respiratory depression should be treated with a starting dose that is slightly higher than that used to reverse other opioids and increased slowly and titrated to reversal of respiratory depression. For example, a starting dose of naloxone of 0.02 mg/kg, or between 1 and 2 mg, is reasonable, and upward titration should not provide doses in excess of about 5 mg without careful consideration and monitoring. Furthermore, because respiratory depression from buprenorphine may outlast the reversal effects of naloxone boluses or short infusions, a continuous infusion of naloxone may be required to maintain respiratory function.

As a partial agonist, buprenorphine has a ceiling effect on respiratory depression in healthy volunteers, with minimal plateau in analgesic effect.³⁵ However, in some patients, despite the ceiling effect, clinically consequential respiratory depression may occur.¹⁷⁹ Data from multiple case series indicate that most buprenorphine-related deaths are associated with concomitant use of other drugs, most often benzodiazepines, or to the IV injection of crushed tablets.¹⁷⁹

The higher affinity (lower K_d) and partial agonism of buprenorphine should allow it to function as an antagonist to the respiratory depressant effects of heroin and improve spontaneous respiration. Although administration of sublingual buprenorphine for opioid overdose is reportedly successful in some case reports,¹⁹⁴ this practice is largely unstudied and not recommended at this time. Interestingly, some reported deaths involved patients given buprenorphine tablets intravenously by fellow drug users for the treatment of heroin-induced respiratory depression.¹³

Unique Opioids

Meperidine. Meperidine, called pethidine outside of the United States, was previously widely used for treatment of chronic and acute pain syndromes. Meperidine produces clinical manifestations typical of the other opioids and may lead to greater euphoria.²⁰¹ Pupillary constriction is less pronounced and, if it occurs, is less persistent than that associated with morphine.⁵⁹ However, normeperidine, a toxic, renally eliminated hepatic metabolite, accumulates in patients receiving chronic high-dose meperidine therapy, such as those with sickle cell disease or cancer. A similar accumulation occurs in patients with kidney disease, in whom the elimination half-life increases from a normal of 14 to 21 hours to 35 hours.¹⁷⁴ Normeperidine causes excitatory neurotoxicity, which manifests as delirium, tremor, myoclonus, or seizures. Based on animal studies, the seizures should not be expected to respond to naloxone.⁶⁰ In fact, experimental evidence suggests that naloxone may potentiate normeperidine-induced seizures, presumably by inhibiting an anticonvulsant effect of meperidine.³⁰ Hemodialysis using a high-efficiency membrane may be of limited clinical benefit but rarely, if ever, is indicated because the toxicity generally is self-limited.

Although primarily an opioid, meperidine is capable of exerting effects at other types of receptors. The most consequential nonopioid-receptor effects occur through the serotonin receptor. Blockade of the presynaptic reuptake of released serotonin may produce serotonin toxicity, which is characterized by muscle rigidity, hyperthermia, and altered mental status, particularly in patients using monoamine oxidase inhibitors (MAOIs) ([Chap. 73](#)). However, dextromethorphan (see Dextromethorphan later) also may produce toxicity. Conversely, the simultaneous use of MAOIs and morphine, fentanyl, or methadone is not expected to produce serotonin toxicity based on the currently appreciated pharmacology of these drugs. Despite its purported (and likely overstated) beneficial effects on biliary tract physiology, meperidine offers little to support its clinical use and has significant disadvantages. Meperidine use has been dramatically reduced or is closely monitored in many institutions and has been eliminated in other centers because of its adverse risk–

benefit profile.

MPTP. In 1982, several cases of acute, severe parkinsonian symptoms were identified in IV drug users.¹⁰⁴ The patients were labeled “frozen addicts” because of the severe bradykinesia, and extensive investigations into the etiology of the problem ensued. This ultimately led to the discovery of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an inadvertent product of presumed errors in the attempted synthesis of the illicit meperidine analog MPPP (1-methyl-4-phenyl-4-propionoxy-piperidine). MPTP is metabolized to the ultimate toxicant MPP⁺ by monoamine oxidase-B in glial cells. Toxicity is inhibited by pretreatment with deprenyl, a monoamine oxidase-B inhibitor. MPP⁺ is a paraquatlike xenobiotic capable of selectively destroying the dopamine-containing cells of the substantia nigra by inhibiting mitochondrial oxidative phosphorylation.¹⁵¹ The index cases initially responded to standard antiparkinsonian therapy, but none improved substantially, and the effects of the medications waned.⁶ Although calamitous for exposed patients, MPTP has proved to be invaluable in the development of experimental models for the study of Parkinson disease. Several of the original “frozen” patients subsequently underwent stereotactic implantation of fetal adrenal tissue grafts into their basal ganglia, with significant clinical improvement.¹⁰⁵

Dextromethorphan. Dextromethorphan is devoid of analgesic properties altogether even though it is the optical isomer of levorphanol, a potent opioid analgesic. Based on this structural relationship, dextromethorphan is commonly considered an opioid, although its receptor pharmacology is much more complex and diversified. At high doses, dextromethorphan does bind to opioid receptors to produce miosis, respiratory depression, and CNS depression. Reversal of these opioid effects by naloxone is reported. Binding to the PCP site on the NMDA receptor and subsequent inhibition of calcium influx through this receptor-linked ion channel causes sedation. This same activity may account for its antiepileptic properties and for its neuroprotective effects in ischemic brain injury. Because NMDA receptor blockade also enhances the analgesic effects of μ -opioid agonists, combination therapy with morphine and dextromethorphan (MorphiDex) has been introduced.

Blockade of presynaptic serotonin reuptake by dextromethorphan may elicit serotonin toxicity in patients receiving MAOIs.¹⁶⁶ Movement disorders, described as choreoathetoid or dystonialike, occasionally occur and presumably result from alteration of dopaminergic neurotransmission. Dextrophan, the active O-demethylation metabolite of dextromethorphan, is produced by CYP2D6, an enzyme with a well-described genetic polymorphism.⁵ Whereas patients with the “extensive metabolizer” polymorphism appear to experience more drug-related psychoactive effects, poor metabolizers experience more adverse effects related to the parent compound.²⁰³

Dextromethorphan is available without prescription in cold preparations, primarily because of its presumed lack of significant addictive potential. However, abuse of dextromethorphan is increasing, particularly among high school students.⁹ This increase in use likely is related to the easy availability of dextromethorphan and its perceived limited toxicity. Common street names include “DXM,” “dex,” and “roboshots.” Users often have expectations of euphoria and hallucinations, but a dysphoria comparable to that of PCP commonly ensues. Reports of substantial cold medicine consumption raise several concerns, including APAP poisoning, opioid dependency, and bromide toxicity.⁸² This last concern relates to the common formulation of dextromethorphan as the hydrobromide salt. At times, the first clue may be an elevated serum chloride concentration when measured on certain autoanalyzers (Chaps. 6 and 19).

Tramadol and Tapentadol. Tramadol (Ultram) and tapentadol (Nucynta) are novel synthetic analgesics with both opioid and nonopioid mechanisms responsible for their clinical effects. Tramadol is a reuptake inhibitor of norepinephrine and 5-HT, and it has an active metabolite, formed via CYP2D6, that is a weak μ opioid receptor agonist.¹³⁹ Tapentadol, which does not require activation, has relatively strong μ -opioid receptor agonism and inhibits the reuptake of norepinephrine but not serotonin.⁷⁰ Both are available in immediate-release and extended-release formulations.

A large number of spontaneous reports to the FDA suggest that therapeutic use of tramadol may cause seizures, particularly on the first day of therapy. However, epidemiologic studies have not confirmed this association.⁵⁶ Tramadol-related seizures are not responsive to naloxone but are suppressed with benzodiazepines. In fact, the package insert cautions against using naloxone in patients with tramadol overdoses because in animals treated with naloxone, the risk of seizure is increased. Correspondingly, one patient in a prospective series had a seizure that was temporally related to naloxone administration.¹⁶⁷ Acute overdose of tramadol is generally considered non-life threatening, and most fatalities were associated with polysubstance overdose. Ultrarapid metabolizers at CYP2D6 may experience complications at conventional doses.⁴⁸ Patients using MAOIs may be at risk for development of serotonin toxicity after taking tramadol.

Tramadol abuse is reported, but its extent is undefined. In a review of physician drug abuse in several states, tramadol was the second most frequent opioid reported.¹⁶² Opioid users recognized tramadol as an opioid only when given in an amount that was six times the therapeutic dose, but at this dose, the users did not develop opioidlike clinical effects such as miosis. Patients may develop typical opioid manifestations after a large overdose. Significant respiratory depression is uncommon and should respond to naloxone.¹⁶⁷ Generally, urine drug screening for drugs of abuse is negative for opioids in tramadol-exposed patients. Tapentadol is relatively new to the market, and although its abuse potential remains concerning and case reports exist,⁹⁴ there are insufficient epidemiologic data to identify diversion or abuse.⁴¹

Propoxyphene. Propoxyphene is a weak analgesic with limited efficacy data and serious safety concerns. Similar to its

structural analog methadone, propoxyphene binds μ -opioid receptors and produces the expected opioid clinical findings. However, unanticipated properties of propoxyphene manifest after overdose. Propoxyphene and its hepatic metabolite, norpropoxyphene, produce myocardial sodium channel blockade identical to the type IA antidysrhythmics. This process results in QRS complex widening and negative inotropy (Chap. 64).

Diphenoxylate and Loperamide. Although diphenoxylate is structurally similar to meperidine, its extreme insolubility limits absorption from the GI tract. This factor may enhance its use as an antidiarrheal agent, which presumably occurs via a local opioid effect at the GI μ receptor. However, the standard adult formulation may result in significant systemic absorption and toxicity in children, and all such ingestions should be deemed consequential. Diphenoxylate is formulated with a small dose (0.025 mg) of atropine (as Lomotil), both to enhance its antidiarrheal effect and to discourage illicit use.

Because both components of Lomotil may be absorbed and their pharmacokinetic profiles differ somewhat, a biphasic clinical syndrome is occasionally noted.¹¹⁵ Patients may manifest atropine poisoning (anticholinergic syndrome), either independently or concomitantly with the opioid effects of diphenoxylate. Delayed, prolonged, or recurrent toxicity is common and is classically related to the delayed gastric emptying effects inherent to both opioids and anticholinergics. However, these effects are more likely explained by the accumulation of the hepatic metabolite difenoxin, which is a significantly more potent opioid than diphenoxylate and possesses a longer serum half-life. Still, the relevance of gastroparesis is highlighted by the retrieval of Lomotil pills by gastric lavage as late as 27 hours after ingestion.

A review of 36 pediatric reports of Lomotil overdoses found that although naloxone was effective in reversing the opioid toxicity, recurrence of CNS and respiratory depression was common.¹¹⁵ This series included a patient with an asymptomatic presentation 8 hours after ingestion who was observed for several hours and then discharged. This patient returned to the ED 18 hours after ingestion with marked signs of atropinism. In this same series, children with delayed onset of respiratory depression and other opioid effects were reported, and others describe cardiopulmonary arrest 12 hours after ingestion. Naloxone infusion may be appropriate for patients with recurrent signs of opioid toxicity. Because of the delayed and possibly severe consequences, all children and all adult patients with potentially significant ingestions should be admitted for monitored observation in the hospital.

Loperamide (Imodium) is another insoluble meperidine analog that is used to treat diarrhea. This medication is available without a prescription, and the paucity of adverse patient outcomes reported in the medical literature suggests that the safety profile of this agent is good.

SUMMARY

- Opioid overdose and toxicity remain major causes of drug-related morbidity and mortality.
- Although the therapeutic and toxic doses of opioids are difficult to predict because of the development of tolerance with chronic use, the primary adverse event from excessive dosing is respiratory depression.
- Thus ventilatory support, or administration of a short-acting opioid antagonist such as naloxone, should be adequate initial therapy.
- An appreciation of the pharmacologic differences between the various opioids allows for the identification and appropriate management of patients poisoned or otherwise adversely affected by these xenobiotics.

Opioid Antagonists

Lewis S. Nelson and Mary Ann Howland

Morphine

Naloxone

Naltrexone

Nalmefene

INTRODUCTION

Naloxone, nalmefene, naltrexone, and methylnaltrexone are pure competitive opioid antagonists at the mu (μ), kappa (δ), and delta (δ) receptors. Opioid antagonists prevent the actions of opioid agonists, reverse the effects of both endogenous and exogenous opioids, and cause opioid withdrawal in opioid-dependent patients. Naloxone is the primary opioid antagonist used to reverse respiratory depression in patients manifesting opioid toxicity. The parenteral dose should be titrated to maintain adequate airway reflexes and ventilation. By titrating the dose, beginning with 0.04 mg and increasing as indicated to 0.4 mg, 2 mg, and finally 10 mg, abrupt opioid withdrawal can be prevented. This titrated low dose method of administration limits withdrawal induced adverse effects, such as vomiting and the potential for aspiration pneumonitis, and a surge in catecholamines with the potential for cardiac dysrhythmias and acute respiratory distress syndrome (ARDS). Because of its poor oral bioavailability, oral naloxone may be used to treat patients with opioid induced constipation. Methylnaltrexone, a parenteral medication, and alvimopan, an oral capsule, are effective in reversing opioid-induced constipation without inducing opioid withdrawal. This is because neither is able to enter the central nervous system (CNS). Naltrexone is used orally for patients after opioid detoxification to maintain opioid abstinence and as an adjunct to achieve ethanol abstinence. Nalmefene, no longer available in the United States, has a duration of action between those of naloxone and naltrexone.

HISTORY

The understanding of structure–activity relationships led to the synthesis of many new molecules in the hope of producing potent opioid agonists free of abuse potential. Although this goal has not yet been achieved, opioid antagonists and partial agonists resulted from these investigations. N-Allyl norcodeine was the first opioid antagonist synthesized (in 1915), and N-allylnormorphine (nalorphine) was synthesized in the 1940s.^{37,66} Nalorphine was recognized as having both agonist and antagonist effects in 1954. Naloxone was synthesized in 1960, and naltrexone was synthesized in 1963. The synthesis of opioid antagonists that are unable to cross the blood–brain barrier (sometimes called peripherally restricted) allowed patients receiving long-term opioid analgesics to avoid opioid induced constipation, one of the most uncomfortable side effects associated with this therapy. Since the mid 1990s, there has been a steady increase in the use of naloxone that has been prescribed or directly dispensed to heroin users for administration by bystanders in case of overdose.¹⁰

PHARMACOLOGY

Chemistry

Minor alterations can convert an agonist into an antagonist. The substitution of the N-methyl group on morphine by a larger functional group led to nalorphine and converted the agonist levorphanol to the antagonist levallorphan.³⁵ Naloxone, naltrexone, and nalmefene are derivatives of oxymorphone with antagonist properties resulting from addition of organic or other functional groups.^{35,39} Relatedly, nalmefene is a 6-methylene derivative of naltrexone.

Mechanism of Action

The μ receptors are responsible for analgesia, sedation, miosis, euphoria, respiratory depression, and decreased gastrointestinal (GI) motility. The δ receptors are responsible for spinal analgesia, miosis, dysphoria, anxiety, nightmares, and hallucinations. The δ receptors are responsible for analgesia and hunger. The currently available opioid receptor antagonists are most potent at the μ receptor, with higher doses required to affect the δ and δ receptors. They all bind to the opioid receptor in a competitive fashion, preventing the binding of agonists, partial agonists, or mixed agonist–antagonists without producing any independent action.

Pharmacokinetics

Naloxone, naltrexone, and nalmefene are similar in their antagonistic mechanism but differ primarily in their pharmacokinetics. Both nalmefene and naltrexone have longer durations of action than naloxone, and both have adequate oral bioavailability to produce systemic effects. Methylnaltrexone can be given orally or parenterally but is excluded from the CNS and only produces peripheral effects. Selective antagonists for μ , δ , and δ are available experimentally and are undergoing investigation.

The bioavailability of sublingual naloxone is only 10%.⁵ In contrast, naloxone is well absorbed by all parenteral routes of administration, including the intramuscular (IM), subcutaneous (SC), endotracheal, intranasal, intralingual, and inhalational (nebulized) routes. The onset of action with the various routes of administration are as follows: intravenous (IV), 1 to 2 minutes; SC, approximately 5.5 minutes; intralingual, 30 seconds; intranasal, 3.4 minutes; inhalational, 5 minutes; endotracheal, 60 seconds; and IM, 6 minutes.^{23,41,53,73} The distribution half-life is rapid (~5 minutes) because of its high lipid solubility. The volume of distribution (Vd) is 0.8 to 2.64 L/kg.³¹

A naloxone dose of 13 µg/kg in an adult occupies approximately 50% of the available opioid receptors.⁵⁴ The duration of action of naloxone is approximately 20 to 90 minutes and depends on the dose of the agonist, the dose and route of administration of naloxone, and the rates of elimination of the agonist and naloxone.^{5,25,68} Naloxone is metabolized by the liver to several compounds, including a glucuronide. The elimination half-life is 60 to 90 minutes in adults and approximately two to three times longer in neonates.

Naltrexone is rapidly absorbed with an oral bioavailability of 5% to 60%, and peak serum concentrations occur at 1 hour.³⁴ Distribution is rapid, with a Vd of approximately 15 L/kg and low protein binding.⁴⁵ Naltrexone is metabolized in the liver to β-naltrexol (with 2%–8% activity) and 2-hydroxy, 3-methoxy-β-naltrexol and undergoes an enterohepatic cycle.⁷² The plasma elimination half-life is 10 hours for β-naltrexone and 13 hours for β-naltrexol, with terminal phases of elimination of 96 hours and 18 hours, respectively.⁷⁰

Nalmefene has an oral bioavailability of 40%, with peak serum concentrations usually reached within 1 to 2 hours.²¹ After SC administration, peak concentrations do not occur for more than 2 hours, although therapeutic concentrations are reached within 5 to 15 minutes. A 1 mg parenteral dose blocks more than 80% of opioid receptors within 5 minutes. The apparent Vd is 3.9 L/kg for the central compartment and 8.6 L/kg at steady state. Protein binding is approximately 45%.²⁰ Nalmefene has a redistribution half-life of 41 ± 34 minutes and a terminal half-life of 10.8 ± 5 hours after a 1 mg IV dose. It is metabolized in the liver to an inactive glucuronide conjugate that probably undergoes enterohepatic recycling, accounting for approximately 17% of drug elimination in the feces. Less than 5% is excreted unchanged in the urine.

Methylnaltrexone is a quaternary amine methylated derivative of naltrexone that is peripherally restricted because of its poor lipid solubility and inability to cross the blood–brain barrier.⁷⁹ After SC administration, peak serum concentrations occur in about 30 minutes. The drug has a Vd of 1.1 L/kg and is minimally protein bound (11%–15%). Although there are several metabolites, 85% of the drug is eliminated unchanged in the urine.⁷⁹

Pharmacodynamics

In the proper doses, pure opioid antagonists reverse all of the effects at the µ, δ, and δ receptors of endogenous and exogenous opioid agonists, except for those of buprenorphine, which has a very high affinity for and slow rate of dissociation from the µ receptor.⁵⁴ Actions of opioid agonists that are not mediated by interaction with opioid receptors, such as direct mast cell liberation of histamine or the potassium channel blocking effects of methadone, are not reversed by these antagonists.² Chest wall rigidity from rapid fentanyl infusion is usually reversed with naloxone.¹⁴ Opioid-induced seizures in animals, such as from propoxyphene, tend to be antagonized by opioid antagonists, although seizures caused by meperidine (normeperidine) and tramadol are exceptions.³⁰ The benefit in humans is less clear. A report of two newborns who developed seizures associated with fentanyl and morphine infusion demonstrated abrupt clinical and electroencephalographic resolution after administration of naloxone.¹⁷

Opioids operate bimodally on opioid receptors.¹⁵ At very low concentrations, µ opioid receptor agonism is excitatory at this receptor and actually may increase pain. This antianalgesic effect is modulated through a G_s protein and usually is less important clinically than the well-known inhibitory actions that result from coupling to a G_o protein at usual analgesic doses. For this reason, extremely low doses of opioid antagonists (ie, 0.25 µg/kg/h of naloxone) enhance the analgesic potency of opioids, including morphine, methadone, and buprenorphine.^{16,29} Naloxone also attenuates or prevents the development of tolerance and dependence.²⁹ Coadministration of these very low doses of antagonists with the opioid also limits opioid-induced adverse effects such as nausea, vomiting, constipation, and pruritus.⁷⁹

The opioid antagonists may reverse the effects of endogenous opioid peptides, including endorphins, dynorphins, and enkephalins. Endogenous opioids are found in tissues throughout the body and may work in concert with other neurotransmitter systems to modulate many physiologic effects.^{26,67} For instance, during shock, the release of circulating endorphins produces an inhibition of central sympathetic tone by stimulating δ receptors within the locus coeruleus, resulting in vasodilation. Vagal tone is also enhanced through stimulation of opioid receptors in the nucleus ambiguus.

Research investigating the cardioprotective effects of opioid agonists through their action at the sarcolemmal and mitochondrial K⁺-ATP (adenosine triphosphate) channels is ongoing.²⁷ Nonselective opioid antagonists may negate these protective effects.

ROLE IN OPIOID TOXICITY

Naloxone has been used for decades by medical personnel for the management of patients with opioid toxicity. Initial studies found the use of naloxone to be relatively safe and highly effective in awakening opioid-toxic patients.^{40,76} Although recommended to be administered empirically to nearly every patient with a depressed level of consciousness and respiratory depression,³⁸ as complications of precipitated opioid withdrawal became more apparent, aggressive use of naloxone has been scaled back.⁶ Currently, the empiric dose that is considered safe for all opioid-dependent patients is

0.04 mg, although in nondependent patients, higher doses may be administered without concern for precipitating withdrawal. The goal of reversal of opioid poisoning is to improve the patient's ventilation while avoiding withdrawal, which is associated with significant complications (see later discussion).

Take-home naloxone programs are developing around the world. In these programs, opioid abusers and their families are supplied naloxone to be administered to others after opioid overdose, generally by the SC (by needle and syringe) or intranasal (by atomizer) route.^{1,42,76} An autoinjector containing 0.4 mg naloxone was approved for IM use in 2014. These bystander programs are credited with saving numerous lives, although the absolute number and rate are unknown.^{10,13} However, concerns exist regarding proper dosing, relative safety, use in mixed overdose (eg, cocaine or benzodiazepine for distinct reasons), attempts to overcome precipitated withdrawal with larger doses of agonist, comfort pushing the opioid dose because of the availability of rescue therapy, risk of arrest with drug paraphernalia (covered in most jurisdictions with Good Samaritan clauses), and refusal of emergency medical services involvement (with subsequent recrudescence of opioid toxicity after naloxone effect wanes). (See Adverse Effects and Safety Issues.)

ROLE IN MAINTENANCE OF OPIOID ABSTINENCE

Opioid dependence is managed by substitution of the abused opioid, typically heroin or a prescription opioid, with methadone or buprenorphine or by detoxification and subsequent abstinence. Maintenance of abstinence is often assisted by naltrexone, although any pure opioid antagonist could be used.⁶² Typically, naltrexone is chosen because of its oral absorption and long duration of action compared with those of naloxone.^{48,62}

Before naltrexone can be administered for abstinence maintenance, the patient must be weaned from opioid dependence and be a willing participant. Naloxone should be administered IV to confirm that the patient is no longer opioid dependent and safe for naltrexone. With naloxone, opioid withdrawal, if it occurs, will be short lived instead of prolonged after use of naltrexone. Naltrexone does not produce tolerance, although prolonged treatment with naltrexone produces up regulation of opioid receptors.⁷⁷

ROLE IN ETHANOL ABSTINENCE

Naltrexone, particularly the IM depot form (Vivitrol), is used as adjunctive therapy in ethanol dependence based on the theory that the endogenous opioid system modulates ethanol intake.⁶⁵ Naltrexone reduces ethanol craving, the number of drinking days, and relapse rates.^{46,57} Naltrexone induces moderate to severe nausea in 15% of patients, possibly as a result of alterations in endogenous opioid tone induced by prolonged ethanol ingestion.

OTHER USES

Poorly orally bioavailable opioid antagonists (eg, naloxone) and peripherally restricted opioid antagonists (eg, methylnaltrexone) are used to prevent or treat the constipation that occurs as a side effect of opioid use, whether for pain management or drug abuse maintenance therapy.⁸ Methylnaltrexone administered SC results in evacuation within 4 hours in nearly half of those who receive the drug for this indication.⁶⁴

Opioid antagonists are sometimes used in the management of overdoses with nonopioids such as ethanol,²² clonidine,⁶¹ captopril,⁶⁹ and valproic acid.⁶³ In none of these instances is the reported improvement as dramatic or consistent as in the reversal of an opioid. The mechanisms for each of these, although undefined, may relate to reversal of endogenous opioid peptides at opioid receptors.

Naloxone has been used to reverse the effects of endogenous opioid peptides in patients with septic shock, although the results are variable.¹⁹ Treatment is often ineffective and may result in adverse effects, particularly in patients who are opioid tolerant. Naloxone may have a temporizing effect via elevation of mean arterial pressure.

Opioid antagonists at low doses are used for treatment of morphine-induced pruritus resulting from systemic or epidural opioids and for treatment of pruritus associated with cholestasis.^{52,55}

ADVERSE EFFECTS AND SAFETY ISSUES

Pure opioid antagonists produce no clinical effects in opioid-naïve or nondependent patients even when administered in massive doses.⁷

When patients dependent on opioid agonists are exposed to opioid antagonists or agonist-antagonists such as pentazocine, they exhibit opioid withdrawal, including yawning, lacrimation, diaphoresis, rhinorrhea, piloerection, mydriasis, vomiting, diarrhea, myalgias, mild elevations in heart rate and blood pressure, and insomnia. Antagonist-precipitated withdrawal may result in an "overshoot" phenomenon, from an increase in circulating catecholamines,

resulting in hyperventilation, tachycardia, and hypertension.⁴⁴ Under these circumstances, there is a potential for related complications such as myocardial ischemia, heart failure, and CNS injury.⁴³ Delirium, although rarely reported in patients withdrawing by opioid abstinence, may occur when an opioid antagonist is used to reverse effects in patients dependent on high doses of opioids or during rapid opioid detoxification.³² These severe manifestations of precipitated opioid withdrawal may occur with ultrarapid opioid detoxification and are associated with fatalities occurring in the postadministration period.³⁶ This rapid form of deliberate detoxification differs significantly from the opioid withdrawal associated with volitional opioid abstinence ([Chap. 15](#)).

Case reports describe ARDS, hypertension, and cardiac dysrhythmias in association with naloxone administration almost uniformly in opioid-dependent patients.^{56,60} The clinical complexities of the setting make it difficult to analyze and attribute these adverse effects solely to naloxone.⁹ ARDS occurs after heroin overdose in the absence of naloxone,²⁴ making the exact contribution of naloxone to the problem unclear. Rather, in certain patients, naloxone may unmask ARDS previously induced by the opioid but unrecognized because of the patient's concomitant opioid-induced respiratory depression.

If the patient's airway is unprotected during withdrawal and vomiting occurs, aspiration pneumonitis may complicate the recovery.¹² Given the frequency of polysubstance abuse and overdose associated with altered consciousness, the risk of precipitating withdrawal associated vomiting should always be a concern.

Resedation is a function of the relatively short duration of action of the opioid antagonist compared with the opioid agonist. Most opioid agonists have durations of action longer than that of naloxone and shorter than that of naltrexone. A long duration of action is advantageous when the antagonist is used to promote abstinence (naltrexone) but is undesired when inappropriately administered to an opioid-dependent patient.

Unmasking underlying cocaine or other stimulant toxicity may explain some of the cardiac dysrhythmias that develop after naloxone-induced opioid reversal in a patient simultaneously using both opioids and stimulants ([Chaps. 76 and 78](#)).⁵⁰

Antagonists stimulate the release of hormones from the pituitary, resulting in increased concentrations of luteinizing hormone, follicle-stimulating hormone, and adrenocorticotrophic hormone and stimulate the release of prolactin in women.⁵⁸

Management of Iatrogenic Withdrawal

Excessive administration of an opioid antagonist to an opioid-dependent patient will predictably result in opioid withdrawal. When induced by naloxone, all that is generally required is protecting the patient from harm and reassuring the patient that the effects will be short lived. Symptomatic care may be necessary on occasion. After inadvertent administration of naltrexone, the expected duration of the withdrawal syndrome generally mandates the use of pharmacologic intervention.^{28,47} Overcoming the opioid receptor antagonism is difficult, but if used in titrated doses, morphine or fentanyl may be successful. Adverse effects from histamine release from morphine and chest wall rigidity from fentanyl should be anticipated. If more moderate withdrawal is present, the administration of metoclopramide, clonidine, or a benzodiazepine is usually adequate.⁴³

What constitutes an appropriate observation period after antagonist administration depends on many factors. After IV bolus naloxone, observation for two hours should be adequate to determine whether sedation and respiratory depression will return. Although no fatalities were identified in medical examiner records after the rapid prehospital release of patients who had presumably overdosed with heroin and were administered naloxone, the true safety of this practice remains questionable.¹¹ Although the matched pharmacokinetics of heroin and naloxone suggests potential utility for such a practice, the high frequency of methadone or sustained-release prescription opioids use in many communities raises concerns. That is, the pharmacokinetic mismatch between naloxone and both methadone and sustained-release oxycodone results in recurrent opioid toxicity and prevents widespread implementation of this program.⁷¹ Similarly, patients on continuous naloxone infusion must be observed for 2 hours or more after its discontinuation to ensure that respiratory depression does not recur.

PREGNANCY AND LACTATION

Naloxone is a pregnancy Category C drug. A risk to benefit analysis must be considered in pregnant women, particularly those who are opioid tolerant, and their newborns. Inducing opioid withdrawal in the mother probably will induce withdrawal in the fetus and should be avoided. Likewise, administering naloxone to newborns of opioid-tolerant mothers may induce neonatal withdrawal and should be used cautiously ([Chaps. 31, 32, and 38](#)).⁵¹

DOSING AND ADMINISTRATION

The initial dose of antagonist depends on the dose of agonist and the relative binding affinity of the agonist and antagonist at the opioid receptors. The presently available antagonists have a greater affinity for the μ receptor than for the δ or κ

receptors. Some opioids, such as buprenorphine, require greater than expected doses of antagonist to reverse the effects at the μ receptor.^{68,75,85,95} The duration of action of the antagonist depends on many drug and patient variables, such as the dose and the clearance of both the antagonist and agonist.

A dose of 0.4 mg of IV naloxone will reverse the respiratory depressant effects of most opioids and is an appropriate starting dose in non opioid-dependent patients. However, this dose in an opioid-dependent patient usually produces withdrawal, which should be avoided if possible. The goal is to produce a spontaneously and adequately ventilating patient without precipitating significant or abrupt opioid withdrawal. Therefore, 0.04 mg IV is a practical starting dose in most patients, increasing to 0.4 mg, 2 mg, and finally 10 mg if the patient has no response at lower doses.⁶ If the patient has no response to 8 to 10 mg, then an opioid is not likely to be responsible for the respiratory depression. The dose in children without opioid dependence is essentially the same as for adults. However, for those with the possibility of withdrawal or recrudescence of severe underlying pain, more gentle reversal with 0.001 mg/kg, with concomitant supportive care, is warranted. Although both the adult and pediatric doses recommended here are lower than those conventionally suggested in other references, the availability of safe and effective interim ventilatory therapy permits these lower doses and lowers the acceptable risk of precipitating withdrawal.

When 1 mg of naloxone is administered IV, it prevents the action of 25 mg of IV heroin for 1 hour, but 50 mg of oral naltrexone antagonizes this dose of heroin for 24 hours; 100 mg of oral naltrexone has a blocking effect for 48 hours, and 150 mg of oral naltrexone is effective for 72 hours.

The use of low doses of IV naloxone to reverse opioid overdose may prolong the time to improvement of ventilation, and during this period, assisted ventilation may be required. The same limitation exists with SC naloxone administration, and the absorbed dose is more difficult to titrate than when administered IV.⁷³ Naloxone can also be administered intranasally, although this route results in the delivery of unpredictable doses. In the prehospital setting, the time to onset of clinical effect of intranasal naloxone is comparable to that of IV or IM naloxone, largely because of the delay in obtaining IV access and slow absorption, respectively.^{3,41} Intranasal naloxone is not recommended as first-line treatment by health care providers.⁴² Nebulized naloxone (2 mg is mixed with 3 mL of 0.9% sodium chloride solution) has similar limitations in dose accuracy and is further limited in patients with severe ventilatory depression, the group most in need of naloxone. Although reports suggest successful use of nebulized naloxone, these patients are not optimal candidates for inhalation therapy because of the likelihood of over- or underdosing of naloxone.⁷⁴ Although needleless delivery is a clear prehospital advantage,⁴⁹ there appears to be little role for hospital use of intranasal or nebulized naloxone by health professionals.

Evaluation for the redevelopment of respiratory depression requires nearly continuous monitoring. Resedation should be treated with either repeated dosing of the antagonist or, in some cases, such as after a long-acting opioid agonist, with another bolus followed by a continuous infusion of naloxone. Two-thirds of the bolus dose of naloxone that resulted in reversal, when given hourly, usually maintains the desired effect.³³ This dose can be prepared for an adult by multiplying the effective bolus dose by 6.6, adding that quantity to 1000 mL, and administering the solution IV at an infusion rate of 100 mL/h. It must be emphasized that if resedation occurs rebolus with the dose of naloxone that provided reversal and titrate the infusion upward. Titration upward or downward is easily accomplished as necessary to both maintain adequate ventilation and avoid withdrawal. A continuous infusion of naloxone is not a substitute for continued vigilance. A period of 12 to 24 hours often is chosen for observation based on the presumed opioid, the route of administration, and the dosage form (sustained release). Body packers are a unique subset of patients who, because the reservoir of drug in the GI tract, require individualized antagonist management strategies (Special Considerations: SC5).

Use of longer acting opioid antagonists, such as naltrexone, places the patient at substantial risk for protracted withdrawal syndromes. The use of a long-acting opioid antagonist in acute care situations should be reserved for carefully considered special indications together with extended periods of observation or careful follow-up. For example, the unintentional ingestion of long acting opioid agonists in naive patients. An oral dose of 150 mg of naltrexone generally lasts 48 to 72 hours and should be adequate as an antidote for the majority of opioid-intoxicated patients. Discharge of opioid-toxic patients after successful administration of a long-acting opioid antagonist, although theoretically attractive, is not well studied. There are concerns about attempts by patients to overcome opioid antagonism by administering high doses of opioid agonist, with subsequent respiratory depression as the effect of the antagonist wanes.

Naltrexone is administered orally in a variety of dosage schedules for treatment of opioid dependence. A common dosing regimen is 50 mg/day Monday through Friday and 100 mg on Saturdays. Alternatively, 100 mg every other day or 150 mg every third day can be administered. The IM extended-release suspension is injected monthly at a recommended dose of 380 mg.

Methylnaltrexone SC dosing for opioid-induced constipation is weight based.⁷⁸ The dose is 0.15 mg/kg for patients who weigh less than 38 kg and more than 114 kg. For patients who weigh between 38 and less than 62 kg, 8 mg is administered, and for those between 62 and 114 kg, 12 mg is provided. Patients with stage 4 or 5 chronic kidney disease should receive half the recommended dose.

Alvimopan (Entereg) is approved by the Food and Drug Administration for the management of postoperative ileus or

constipation in the hospital setting. The dose is 12 mg orally 0.5 to 5 hours before surgery. The day after surgery, the maintenance dosage is 12 mg twice a day. The total maximum number of doses is 15 during hospitalization.

Buprenorphine

Naloxone reverses the respiratory depressant effects of buprenorphine in a bell-shaped dose–response curve.^{18,59,68,75}

Bolus doses of naloxone of 2 to 3 mg followed by a continuous infusion of 4 mg/h in adults were able to fully reverse the respiratory depression associated with IV buprenorphine administered in a total dose of 0.2 and 0.4 mg over 1 hour.⁶⁸

Reversal was not apparent until about 45 to 60 minutes after the infusion. A reappearance of respiratory depression occurred when the naloxone infusion was stopped because the distribution of naloxone out of the brain and its subsequent elimination from the body are much faster than those of buprenorphine. Consistent with a bell-shaped response curve, doses of naloxone greater than 4 mg/h actually led to the recurrence of respiratory depression. It is postulated that buprenorphine has differential effects on the μ opioid receptor subtypes (Chap. 38), with agonist activity at low doses and antagonist action at high doses. Therefore, excess naloxone antagonizes the antagonistic effects of buprenorphine, worsening respiratory depression.

FORMULATION AND ACQUISITION

Naloxone (Narcan) for IV, IM, or SC administration is available in concentrations of 0.4 and 1.0 mg/mL with and without parabens in 1 and 2 mL ampoules, vials, and syringes and in 10 mL multidose vials with parabens. Naloxone can be diluted in 0.9% sodium chloride solution or 5% dextrose to facilitate continuous IV infusion. Naloxone is stable in 0.9% sodium chloride solution at a variety of concentrations for up to 24 hours.

Naltrexone (Revia, Trexan) is available as a 50-mg capsule-shaped tablet. It is also available as a 380 mg vial for reconstitution with a carboxymethylcellulose and polysorbate diluent to form an injectable suspension intended for monthly IM administration (Vivitrol).

Methylnaltrexone (Relistor) is available as a 12-mg/0.6 mL solution for SC injection.⁶⁷ Alvimopan is available as a 12-mg capsule.

SUMMARY

- Naloxone, naltrexone, and methylnaltrexone are pure competitive opioid antagonists at the μ , δ , and δ receptors. Methylnaltrexone does not enter the CNS.
- Naloxone is the primary opioid antagonist used to reverse respiratory depression in patients manifesting opioid toxicity.
- This titrated low dose method of administration, starting at 0.04 mg in an adult, limits withdrawal-induced adverse effects, such as vomiting and the potential for aspiration pneumonitis, and a surge in catecholamines with the potential for cardiac dysrhythmias and ARDS.
- Naltrexone is used orally for patients after opioid detoxification to maintain opioid abstinence and as an adjunct to achieve ethanol abstinence.

39 SALICYLATES

Daniel M. Lugassy

HISTORY AND EPIDEMIOLOGY

The Ancient Egyptians recognized the pain-relieving effects of concoctions made from myrtle and willow leaves. Hippocrates may have been among the first to use willow bark and leaves from the *Salix* species to relieve fever, but it was not until 1829 that the glycoside salicin was extracted from the willow bark and used as an antipyretic. Seven years later, salicylic acid was isolated, and by the late 1800s, it was being used to treat gout, rheumatic fever, and elevated temperatures. The less irritating acetylated salicylate compound was first synthesized in 1833, and in 1899 acetylsalicylic acid was commercially introduced as aspirin by Bayer. With that, the modern era of aspirin therapy and salicylate toxicity began.

The American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) collects and reports annual exposure data in the United States. Analgesics, which include both aspirin and acetaminophen (APAP), continue to rank first among pharmaceuticals most frequently reported in human exposures ([Chap. 136](#)). Salicylate toxicity and fatalities have long been a major toxicological “concern.” From the 1950s to 1970s, salicylate was the leading cause of fatal childhood poisoning. The association with Reye syndrome; safer packaging; and the increased use of nonsteroidal antiinflammatory drugs (NSAIDs), APAP, and other alternatives to aspirin has decreased the incidence of unintentional salicylate poisoning. In the last 5 years of data available (2008–2012), there were 20 to 30 deaths per year reported ([Chap. 136](#)). Despite this decline in reported deaths and general use, it is still imperative that clinicians are adept at early recognition and swift management of patients with salicylate overdose.

Aspirin and other salicylate containing products continue to be some of the most common prescription and nonprescription xenobiotics used by the general public. Since landmark trials demonstrated the inhibition of platelet function by aspirin in the 1970s, its use became the standard of care for cardiovascular disease prevention and treatment. Subsequent investigations have demonstrated that aspirin can decrease the incidence of myocardial infarction, colon cancer, and transient ischemic attack. Its antiinflammatory properties have also continued to make it an active investigational xenobiotic for cancer.¹

Bayer, a company once associated exclusively with aspirin, several years ago turned to making products containing ibuprofen or APAP. But in a very recent move of re-branding, Bayer is now marketing a return of aspirin for pain relief with three new products containing aspirin alone; aspirin with caffeine; and aspirin, caffeine, and APAP. Salicylates continue to be readily available and will continue to lead to significant morbidity and mortality in overdose.

PHARMACOLOGY

Aspirin and other salicylates have analgesic, antiinflammatory, and antipyretic properties, a combination of traits shared by all of the NSAIDs ([Chap. 37](#)). Most of the beneficial effects of NSAIDs result from their inhibition of cyclooxygenase (COX). This enzyme enables the synthesis of prostaglandins, which in turn mediate inflammation and fever.^{116,136}

Contributing to the antiinflammatory effects and independent of the effects on prostaglandins, salicylates and other NSAIDs may also directly inhibit neutrophils.⁹ There are two types of salicylic acid esters, phenolic esters such as aspirin and carboxylic acid esters, including methyl salicylate, phenyl salicylate, and glycosalicylate.²⁶ Most of the studies of salicylate metabolism involve aspirin.²⁶ There is an implicit assumption that all members of the salicylate class have similar properties after being converted to salicylic acid.

Salicylates and NSAIDs are purportedly most effective in treating the pain accompanying inflammation and tissue injury. Such pain is elicited by prostaglandins liberated by bradykinin and other cytokines. Fever is also mediated by cytokines such as interleukin (IL)-1 β , IL-6, α and β interferons, and tumor necrosis factor- α , all of which increase synthesis of prostaglandin E₂. In turn, this inflammatory mediator increases cyclic adenosine monophosphate (cAMP), which triggers the hypothalamus to elevate the body temperature set point, resulting in increased heat generation and decreased heat loss.¹⁰⁸

Because platelets cannot regenerate COX-1, a daily dose of as little as 30 mg of aspirin inhibits COX-1 for the 8- to 12-day lifespan of the platelet.¹⁰⁸ Adverse effects of aspirin and some NSAIDs related to alteration of COX include gastrointestinal (GI) ulcerations and bleeding, interference with platelet adherence,¹⁰⁹ and a variety of metabolic and organ-specific effects described later.

To achieve an antiinflammatory effect for patients with chronic conditions such as rheumatoid arthritis, salicylates are primarily prescribed in doses sufficient to achieve a serum salicylate concentration between 15 and 30 mg/dL, which is considered the therapeutic range. Concentrations higher than 30 mg/dL are typically associated with signs and symptoms of toxicity.

PHARMACOKINETICS

Aspirin is rapidly absorbed from the stomach. The pK_a of aspirin is 3.5, and the majority is nonionized (ie, acetylsalicylic acid) in the strongly acidic stomach (pH 1–2).^{26,56} Although absorption of acetylsalicylate may be less efficient in the small bowel because of its higher pH, it is substantial and rapid because of the large surface area and the fact that the increase in pH increases the solubility of acetylsalicylate.^{84,85} After ingestion of therapeutic doses of immediate release acetylsalicylate, significant serum concentrations are achieved in 30 minutes, and maximum concentrations are often attained in less than 1 hour.²⁶

The plasma half-life of aspirin is about 15 minutes, because it is rapidly hydrolyzed to salicylate. The apparent half-life for salicylate is about 2 to 3 hours at antiplatelet doses and increases to 12 hours at antiinflammatory doses demonstrates dose dependent elimination.⁸⁸ Aspirin undergoes biotransformation in the liver and is then eliminated by the kidneys. The apparent volume of distribution (Vd) increases from 0.2 L/kg at low concentrations to 0.3 to 0.5 L/kg at higher concentrations.^{73,74,117}

TOXICOKINETICS

In overdose, several factors contribute to significantly altered pharmacokinetics that can present very challenging obstacles to effectively managing patients poisoned with salicylates. The dose obviously is critical in contributing to the magnitude and duration of toxicity, but other important factors include the formulation, rate of gastric emptying, bezoar formation, hepatic and renal function, and both the serum and urine pH.

There is a decrease in protein (albumin) binding from 90% at therapeutic concentrations to less than 75% at toxic concentrations caused by saturation of protein binding sites.^{2,11,33} Salicylates have substantially longer apparent half-lives at toxic concentrations than at therapeutic concentrations, varying from 2 to 4 hours at therapeutic concentrations to as long as 20 hours at toxic concentrations.^{28,73} The dosage form of salicylates (eg, effervescent, enteric coated) influences the absorption rate.^{107,110,131} Therapeutic doses of enteric-coated tablets may not produce peak serum concentrations until 4 to 6 hours after ingestion, and in overdose the peak may not be reached until 24 hours after ingestion.^{34,131} Delayed absorption of aspirin may result from salicylate induced pylorospasm or pharmacobezoar formation.^{11,107,113}

Salicylates are conjugated with glycine and glucuronides in the liver and are eliminated by the kidneys. Approximately 10% of salicylates are excreted in the urine as free salicylic acid, 75% as salicyluric acid, 10% as salicylic phenolic glucuronides, 5% as acylglucuronides, and 1% as gentisic acid¹⁰⁸ (Fig. 39–1). As the concentration of salicylates increases, two of the five pathways of elimination—those for salicyluric acid and the salicylic phenolic glucuronide—become saturated and exhibit zero-order kinetics. As a result of this saturation, overall salicylate elimination changes from first-order kinetics to zero-order kinetics^{73,74} (Chap. 9). In a healthy adult, these altered saturation kinetics may occur after as little as 1 to 2 g of acute aspirin ingestion.⁷³

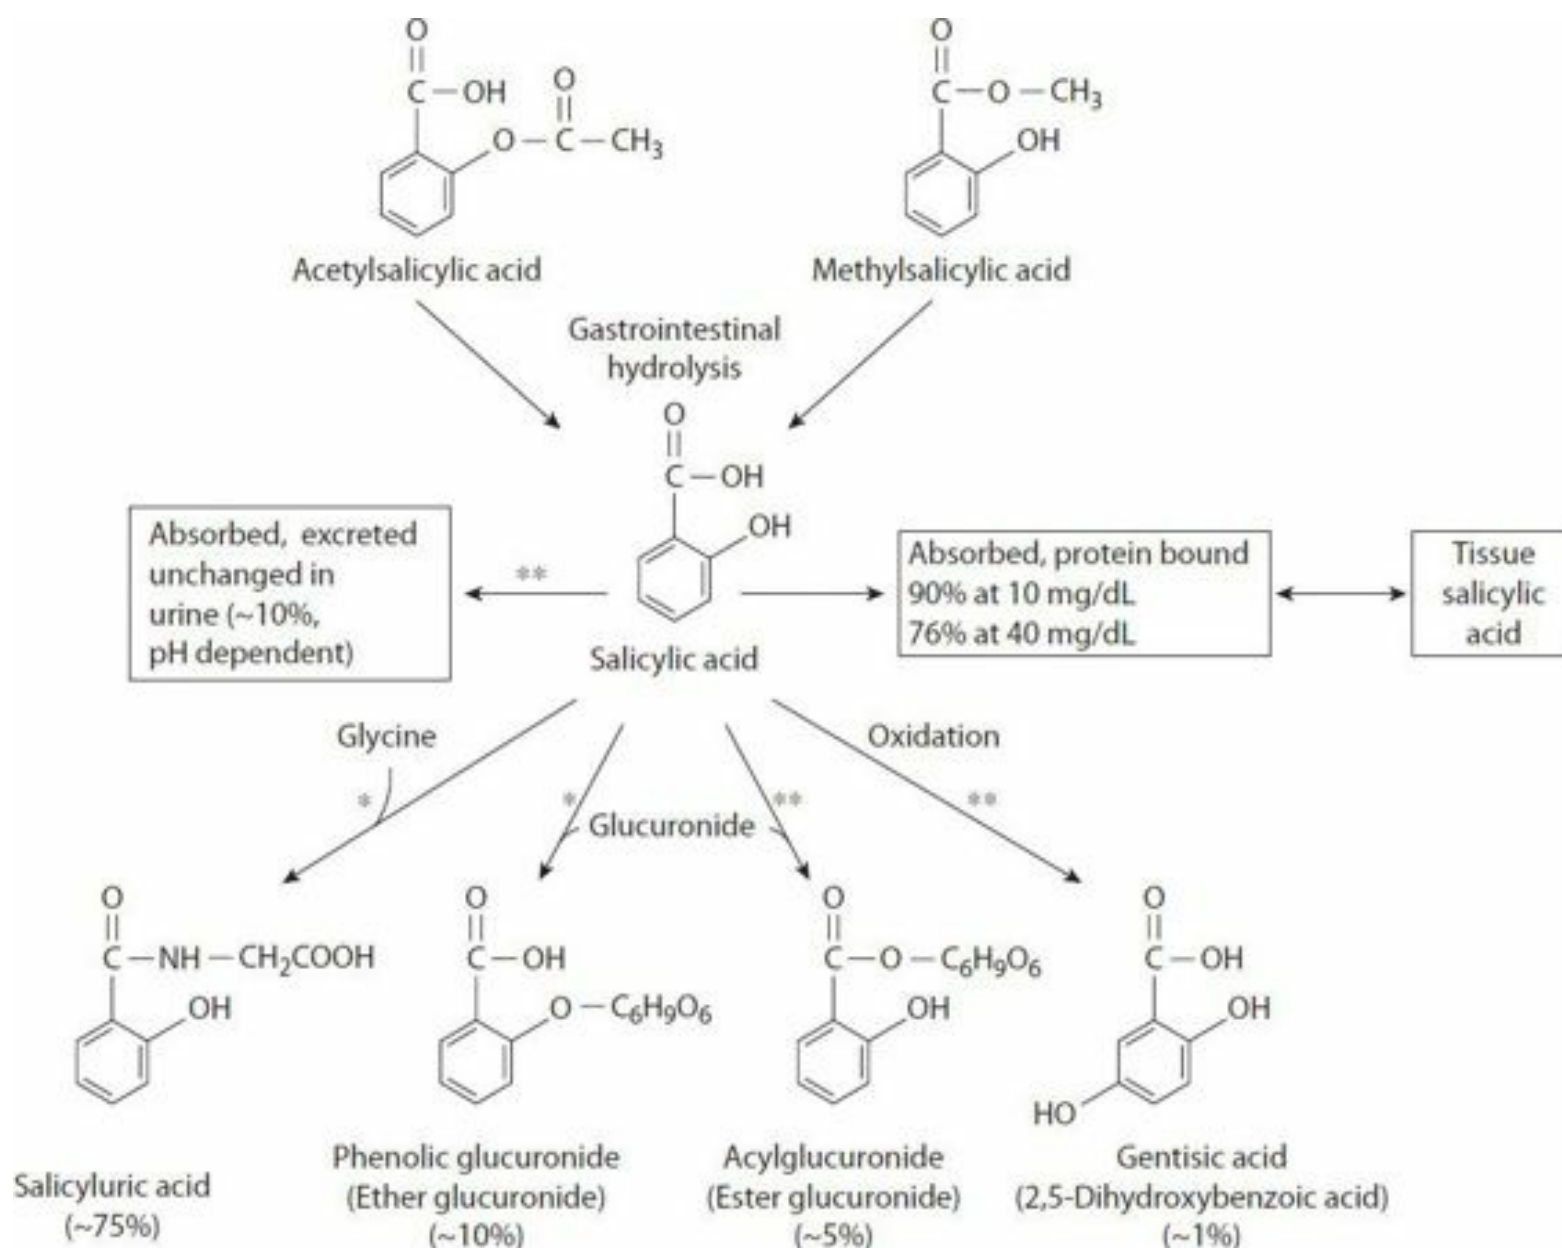

FIGURE 39–1. Salicylic acid metabolism. At excessive doses, the four mechanisms of salicylic acid metabolism are overloaded, leading to increased tissue binding, decreased protein binding, and increased excretion of unconjugated salicylic acid. Asterisk indicates Michaelis-Menten kinetics; double asterisk indicates first-order kinetics.

When administered chronically, a small increase in dosage or a small decrease in metabolism or elimination may result in substantial increases in serum salicylate concentrations and the risk of toxicity.⁶⁵ At very high serum concentrations, salicylate elimination may again resemble first-order elimination as an increasing fraction undergoes renal clearance.

Free salicylic acid is filtered through the glomerulus and is both passively reabsorbed and actively secreted from the proximal tubules. More than 30% of an ingested salicylate dose may be eliminated in alkaline urine and as little as 2% in acidic urine.¹²⁷ Salicylate conjugates (glycine and glucuronides) are filtered and secreted by the proximal tubules; salicylate conjugates are not reabsorbed across renal tubular cells because of limited lipid solubility, and the amount eliminated depends on the glomerular filtration rate and proximal tubule secretion but not urine pH. Protein-binding abnormalities, urine and plasma pH variations, and delayed absorption all influence both the maximum salicylate concentration and the rate of decline.^{85,107}

Other Forms of Salicylate

Topical Salicylate, Methyl Salicylate (Oil of Wintergreen), and Salicylic Acid. Topical salicylates, which are used as keratolytics (salicylic acid) or as rubefacients ($\leq 30\%$ methyl salicylate), are rarely responsible for salicylate poisoning when used in their intended manner because absorption through normal skin is very slow. However, particularly in children, extensive application of topical preparations containing methyl salicylate may result in poisoning.^{14,129} After 30 minutes of contact time, only 1.5% to 2.0% of a dose is absorbed, and even after 10 hours of contact with the methyl salicylate, only 12% to 20% of the salicylate is systemically absorbed.¹⁴ Heat, occlusive dressings, young age, inflammation, and psoriasis all increase topical salicylate absorption.^{16,17} In a study of healthy volunteers, a profound effect of transdermal absorption of methyl salicylate was demonstrated from exercise and heat exposure, with a threefold increase

in the systemic availability of salicylate.²⁵

Ingestion of methyl salicylate may be disastrous because 1 mL of 98% oil of wintergreen contains an equivalent quantity of salicylate as 1.4 g of aspirin. The minimum toxic salicylate dose of approximately 150 mg/kg body weight can almost be achieved with 1 mL of oil of wintergreen, which represents 140 mg/kg of salicylates for a 10-kg child. In Hong Kong, medicated oils containing methyl salicylate accounted for 48% of acute salicylate poisoning cases treated in one hospital.¹⁶ Methyl salicylate is rapidly absorbed from the GI tract, and much, but not all, of the ester is rapidly hydrolyzed to free salicylates. Despite rapid and complete absorption, serum concentrations of salicylates are much less than predicted after ingestion of methyl salicylate containing liniment compared with oil of wintergreen.¹²⁹ Vomiting is common, along with abdominal discomfort. The onset of symptoms usually occurs within 2 hours of ingestion.¹⁷ Patients with methyl salicylate exposure have died in less than 6 hours, emphasizing the need for early determinations of salicylate concentrations in addition to frequent testing after such exposures.

Bismuth Subsalicylate. Bismuth subsalicylate, which is available in several nonprescription formulations, releases the salicylate moiety in the GI tract, where it is subsequently absorbed. Each milliliter of common liquid preparations of bismuth subsalicylate contains 8.7 mg of salicylic acid.³⁹ After a large therapeutic dose (60 mL), peak salicylate concentrations may reach 4 mg/dL at 1.8 hours after ingestion.³⁹ Patients with diarrhea and infants with colic using large quantities of bismuth subsalicylate may develop salicylate toxicity.¹²⁵ Chronic use should also raise concerns for bismuth toxicity (Chap. 90).

PATHOPHYSIOLOGY

Because salicylic acid is a weak acid, at physiologic pH, it exists predominantly in a charged (ionized) state (Chap. 12). But in overdose as the serum pH falls, more salicylate shifts toward a nonionized (uncharged) salicylic acid form that is highly permeable, allowing swift movement across lipid bilayers and cell membranes. This is an important effect in that it allows salicylic acid to enter cells exerting its toxic effects across a wide variety of organs and is discussed later as a target for management.

Acid–Base and Metabolic Effects

Salicylate interferes with the Krebs cycle, which limits production of adenosine triphosphate (ATP).⁶³ It also uncouples oxidative phosphorylation, causing accumulation of pyruvic and lactic acids and releasing energy as heat⁶⁸ (Chaps. 12 and 13). Salicylate-induced increases in fatty acid metabolism generates ketone bodies, including β -hydroxybutyric acid, acetoacetic acid, and acetone. Toxic concentrations of salicylate impair renal hemodynamics, leading to the accumulation of inorganic acids. The net result of all of these metabolic processes is an anion gap metabolic acidosis (Chap. 19) in which the unmeasured anions include salicylate and its metabolites, lactate, ketoacids, and inorganic acids.

The salicylate effect on glucose metabolism is variable and may depend on the severity and phase of toxicity. Salicylate administration in mice increases glycogenolysis and can result in hyperglycemia.¹¹⁵ Early adrenergic effects of acute salicylate toxicity may stimulate epinephrine and glucagon release, enhancing glycogenolysis as well as gluconeogenesis. But salicylate can inhibit alanine and aspartate aminotransferase, and both enzymes provide key amino acid substrates for gluconeogenesis. Hypoglycemia may also occur because of the combined effect of increased energy demands, depletion of glycogen stores, and decreased gluconeogenesis.¹⁰⁴

Salicylate poisoned mice had dramatic increases in serum lactate concentration compared with control mice, likely because of increased glycogenolysis and anaerobic glycolysis to compensate partly for the energy loss caused by uncoupling of oxidative phosphorylation.^{53,83} There was also a marked increase in oxygen consumption in mice even with low salicylate concentrations, highlighting the importance of salicylate induced uncoupling of oxidative phosphorylation.⁵⁴ Several investigations using intact or fragmented mitochondria demonstrate that increasing concentrations of salicylate result in decreased phosphate uptake and a concomitant decrease in the phosphate/oxygen (P/O) ratio.^{83,94} The impaired P/O ratio demonstrates the inefficiency of ATP production by illustrating that the rate of phosphate incorporation into ATP per molecule falls despite oxygen consumed during oxidative phosphorylation. Salicylates reduce lipogenesis by blocking the incorporation of acetate into free fatty acids and increase peripheral fatty acid metabolism as an energy source, resulting in ketone formation. Salicylate-induced increased fatty acid metabolism generates ketone bodies, including β -hydroxybutyric acid, acetoacetic acid, and acetone.

NEUROLOGIC EFFECTS

The central nervous system (CNS) effects are the most visible and most consequential clinical effects in salicylate-poisoned patients. With increasing CNS salicylate concentrations, neuronal energy depletion likely develops as salicylate uncouples neuronal and glial oxidative phosphorylation.⁸³ Several other mechanisms also likely contribute to the neurotoxic

effects of salicylates. Salicylate also causes release of apoptosis inducing factor (AIF) or cytochrome C, triggers p38 mitogen, activated protein kinase, and activates glial caspase-3, which are responsible for programmed neuronal cell death.¹⁰⁵ It is likely that these effects in addition to severe cellular acidosis lead to neuronal dysfunction and ultimately cerebral edema.

Salicylate poisoning may produce a clinical discordance between serum and cerebrospinal fluid (CSF) glucose concentrations.¹⁰⁴ Despite normal serum glucose concentrations, CSF glucose concentration decreased 33% in salicylate-poisoned mice compared with control mice.¹²³ In other words, the rate of CSF glucose use exceeded the rate of supply even in the presence of a normal serum glucose concentration. This hypoglycorrhachia demonstrates that altered glucose metabolism and transport may also play a role in the deleterious neurologic effects of salicylate poisoning. Salicylate-poisoned mice have lower CSF glucose concentrations compared with control mice but can maintain similar concentrations of ATP by enhanced glycolysis. Administration of dextrose in these salicylate-poisoned mice suppressed clinical signs of toxicity underlying the importance of providing supplemental glucose despite normal serum concentrations as discussed later in the management of toxicity.¹²³

Hepatic Effects

Hepatic injury from either acute or chronic overdose of salicylate is rare. Although the hepatocyte is the location of its toxic effects on several metabolic pathways such as glycogenolysis and the Krebs cycle, other concurrent co-ingestants and causes should be considered if there is a clinically significant elevation of aminotransferases or bilirubin concentration or signs of acute liver failure.¹³⁴

An unavoidable historical link exists between the hepatic encephalopathy in Reye syndrome and aspirin. A buildup of fatty acids in the hepatocyte resulting in microvesicular steatosis is characteristic of Reye syndrome. This may occur through salicylate depletion of intrahepatocyte coenzyme A (Co-A), where fatty acids entering the hepatocyte cytoplasm cannot be transported into the mitochondria for β -oxidation. Although there is no mechanism to explain why aspirin has a causal relationship in Reye syndrome, it is clear from epidemiologic evidence that aspirin is an essential cofactor among others in the development of this syndrome.⁴⁶

Otolaryngologic Effects

The molecular mechanism of salicylate ototoxicity is not completely understood but appears to be multifactorial. Inhibition of cochlear COX by salicylate increases arachidonate, enabling calcium flux and neural excitatory effects of N-methyl-D-aspartic acid (NMDA) on cochlear spinal ganglion neurons.^{100,101,112} Also, the prevention of prostaglandin synthesis interferes with the Na^+ - K^+ -adenosine triphosphatase (ATPase) pump in the stria vascularis, and the vasoconstriction decreases cochlear blood flow.^{12,15,37,61} Membrane permeability changes cause a loss of outer hair cell turgor in the organ of Corti, which may impair otoacoustic emissions.^{100,102} A more complete description of the pathophysiology of salicylate-induced ototoxicity and sensorineural alterations as well as comparisons with the patterns of other ototoxic xenobiotics can be found in [Chap. 26](#).

Pulmonary Effects

Salicylates have very potent stimulatory effects on respiratory drive via several mechanisms. Direct stimulation of the medullary respiratory neurons produces hyperpnea and tachypnea even at therapeutic concentrations. In fact, in a human trial, salicylates decreased the number and duration of apneic events in patients with sleep apnea.⁹⁶ Increased sensitivity to PCO_2 and pH further increases ventilation. Carotid body and peripheral arterial chemoreceptor stimulation also contribute to salicylate-induced hyperventilation.⁸¹

Patients with either acute or chronic salicylism may develop acute respiratory distress syndrome (ARDS). It is often a sign of severe and advanced toxicity and can be lethal. One study¹⁰⁶ that summarized data from nearly 400 consecutive cases of salicylate toxicity reported in the literature^{4,51,122,128} concluded that ARDS occurred in approximately 7% of cases. The development of ARDS in salicylate poisoning is associated with a history of cigarette smoking, chronic overdose, metabolic acidosis, and neurologic symptoms at the time of arrival.⁹⁰

Although the exact etiology of salicylate-induced ARDS is unclear, as with other etiologies ARDS can result from increased pulmonary capillary permeability and subsequent exudation of high-protein edema fluid into the interstitial or alveolar spaces.⁵⁷ Adrenergic excess in salicylate poisoning may injure the hypothalamus, leading to a shift in blood from the systemic to the pulmonary circulation because of a loss of left ventricular compliance with left atrial and pulmonary capillary hypertension ([Chap. 17](#)). Additionally, the resulting hypoxia produces pulmonary arterial hypertension and a local release of vasoactive substances, worsening ARDS.⁵⁸ Unventilated salicylate-poisoned sheep were more likely to develop ARDS compared with a mechanically ventilated control group, suggesting that the mechanical stress of prolonged and severe hyperventilation is a significant contributing factor to this complication.⁷⁸

Gastrointestinal Effects

Salicylate disrupts the mucosal barrier that normally protects the gastric lining from the extremely acidic contents of the stomach. GI injury leading to ulcers or bleeding are among the most common adverse effects from therapeutic use of aspirin, but in acute overdose, the most common manifestations result from local gastric irritation presenting with nausea and vomiting. Emesis appears to be triggered both by local mucosal irritation and central stimulation of the chemoreceptor trigger zone.¹⁰ Hemorrhagic gastritis, decreased gastric motility, and pylorospasm result from the direct gastric irritant effects of salicylates.¹¹⁰

Renal Effects

The kidneys play a major role in the excretion of salicylate and its metabolites. Although some believe that salicylates are nephrotoxic, the majority of experimental evidence does not strongly support this notion.^{24,35,95} Most of the adverse renal effects historically associated with salicylates occurred with use of combination products such as aspirin–phenacetin–caffeine (APC) tablets and appear to have been mostly caused by the phenacetin.³⁵ Renal papillary necrosis and chronic interstitial nephritis, initially characterized by reduced tubular function and reduced concentrating ability, rarely occur in adults using salicylates unless they have chronic illnesses that already compromise renal function.

Volume losses in patients with salicylate toxicity that develop from hyperventilation and hyperthermia may also cause prerenal acute kidney injury (AKI). Rarely, salicylates may also induce a Fanconilike syndrome with generalized proximal tubular dysfunction characterized by glucosuria (despite normal serum glucose), proteinuria, aminoaciduria, and uric acid wasting.¹²⁴

Hematologic Effects

The hematologic effects of salicylate poisoning include hypoprothrombinemia and platelet dysfunction.⁹³ The platelet dysfunction, caused by irreversible acetylation of COX-1 and COX-2, prevents the formation of thromboxane A₂, which is normally responsible for platelet aggregation. Although the platelets are numerically and morphologically intact, they are unresponsive to thrombogenic stimulation. At supratherapeutic doses, salicylate decreases the plasma concentration of the γ -carboxyglutamate containing coagulation factors and an accumulation of microsomal substrates for vitamin K dependent carboxylase in the liver and in the lung.¹¹¹ The result of this interruption of vitamin K cycling is similar to that of warfarin,⁹² leading to hypoprothrombinemia (factor II) as well as decreases in factors VII, IX, and X (Chap. 60).

CLINICAL MANIFESTATIONS OF SALICYLATE POISONING

The following sections describe the typical clinical manifestations that follow toxic exposures to salicylates. The natural course of acute ingestions begins with nonspecific GI symptoms, early tachypnea caused by direct central respiratory stimulation, development of an anion gap metabolic acidosis, and several minor neurologic sequelae. As the acidosis worsens, symptoms progress and will invariably evolve to severe CNS toxicity. Hyperthermia, cerebral edema, coagulopathy, ARDS, and severe acidemia are the gravest clinical consequences and are often preterminal events. Cerebral edema is often seen at autopsy in those who succumb to salicylate toxicity.

The earliest signs and symptoms of salicylate toxicity, which include nausea, vomiting, diaphoresis, and tinnitus, typically develop within 1 to 2 hours of acute exposure.^{12,44} But the type of salicylate containing preparation, comorbidities, co-ingestants, and compromise in renal or hepatic function may alter the onset of symptoms that can be delayed up to 24 hours after exposure.¹¹⁰ Case reports of enteric-coated aspirin tablet ingestions have demonstrated delays in symptom onset and time to initial detectable salicylate concentration, with peak salicylate concentrations reported to occur 2 to 3 days after initial exposure.^{31,131}

Acute Salicylate Toxicity

Salicylates are extremely irritating to the GI lining; early vomiting after ingestion may be a warning sign of a clinically significant ingestion. Emesis occurs both by direct GI irritation and from salicylate-induced stimulation of the chemoreceptor trigger zone.¹⁰ Pylorospasm, delayed gastric emptying, and decreased GI motility can all be present, complicating toxicity by altering absorption kinetics. Hemorrhagic gastritis also occurs, likely as a consequence of severe emesis and alteration of protective GI barriers.

The initial evaluation of a patient suspected of salicylate poisoning must start at the bedside with a thorough assessment of the respiratory rate and depth. Subtle tachypnea or hyperpnea should not be overlooked because if missed, delays may occur in the initiation of appropriate laboratory analysis and management. Direct central stimulation of the respiratory center increases minute ventilation, determined by the product of respiratory rate and tidal volume. A primary respiratory alkalosis predominates initially, although an anion gap metabolic acidosis begins to develop early in the course of

salicylate toxicity. By the time a symptomatic adult patient presents to the hospital after a salicylate overdose, a mixed acid–base disturbance is often prominent.⁴⁴ This latter finding includes two primary processes, respiratory alkalosis and metabolic acidosis, and is discernible by arterial blood gas (ABG) or venous blood gas (VBG) and serum electrolyte analyses. In one study of 66 salicylate-poisoned adults, 22% had respiratory alkalosis, and 56% had mixed respiratory alkalosis and metabolic acidosis.⁴⁴

On presentation, salicylate poisoned adults who demonstrate respiratory acidosis should alert the clinician to the fact that systemic toxicity is severe. This patient may be late in the clinical course of poisoning and have salicylate induced ARDS, fatigue from hyperventilating for a prolonged period of time, or CNS depression (from either salicylate itself or co-ingestants). These broad variations of clinical toxicity can be divided into three general time frames based on rapidly available laboratory testing. Early, middle, and late salicylate poisoning are demonstrated in [Table 39–1](#).

TABLE 39–1. Acid-Base Stages of Salicylate Toxicity

Early: Respiratory alkalosis, alkalemia, and alkaluria

Middle: Respiratory alkalosis, metabolic acidosis, alkalemia, and aciduria

Late: Metabolic acidosis with either a respiratory alkalosis or respiratory acidosis, aciduria, and acidemia

Mixed overdoses are common; in one study, one-third of patients with a presumed primary salicylate overdose had taken other xenobiotics.⁴⁴ Benzodiazepines, barbiturates, alcohol, and cyclic antidepressants all blunt the centrally induced hyperventilatory response to salicylates, resulting in either actual respiratory acidosis ($\text{PCO}_2 > 40$ mm Hg) or metabolic acidosis without some respiratory compensation ($\text{PCO}_2 < 40$ mm Hg but inappropriately high for the concomitant degree of metabolic acidosis). In both adults and children, the development of respiratory acidosis may occur as salicylate poisoning progresses. The combination of metabolic and respiratory acidosis in a salicylate poisoning results in severe and worsening acidemia that is an exceedingly grave situation and almost invariably is a preterminal event.⁹⁸

When clinical and radiographic manifestations of ARDS are observed in the setting of salicylate toxicity, the following conditions should be considered: aspiration pneumonitis, viral and bacterial infections, neurogenic ARDS, and salicylate-induced ARDS^{58,64} ([Chap. 29](#)). In 111 consecutive patients with peak salicylate concentrations above 30 mg/dL, ARDS occurred in 35% of patients older than 30 years of age and none of the 55 patients younger than 16 years of age. Risk factors for developing ARDS included cigarette smoking, chronic salicylate ingestion, and the presence of neurologic symptoms on admission. The average arterial blood pH was 7.37 in the six adult patients with ARDS and 7.46 in the 30 adults without ARDS. There was no significant difference in salicylate concentrations, which were approximately 57 mg/dL in both groups.¹²⁸ In a 2-year review of all salicylate deaths in Ontario, Canada, 59% of 39 autopsies revealed pulmonary pathology, mostly “pulmonary edema” (ARDS).⁸⁰

Although hyperventilation is centrally mediated, patients may develop a spectrum of CNS abnormalities that includes confusion, agitation, and lethargy and then ultimately seizures and coma. Human and animal evidence suggests that hypoglycorrhachia despite euglycemia contributes to the neurotoxic effects. Stupor, coma, and delirium have been acutely reversed by the administration of dextrose in children and adults with salicylate toxicity and normal serum glucose concentrations. In one report, a child underwent lumbar puncture, and CSF analysis demonstrated no detectable glucose.²³ The most severe neurologic clinical findings are likely associated with the development of cerebral edema and portend a poor prognosis. Excluding effects on ventilation, signs of neurologic toxicity, even if mild, should be of great concern.

Tinnitus, a subjective sensation of ringing or hissing with or without hearing loss, loss of absolute acoustic sensitivity, and alterations of perceived sounds are the three effects resulting from exposure to large doses of salicylates.¹⁵ The pattern of salicylate-induced auditory sensorineural alterations is different than that of other ototoxic xenobiotics.¹⁵ Tinnitus should demonstrate to clinicians that CNS toxicity has occurred even without alterations in mental status. As CNS salicylate concentrations increase, tinnitus is rapidly followed by diminished auditory acuity that sometimes leads to deafness.¹² As acute toxicity progresses, other CNS effects may include vertigo, hyperactivity, agitation, delirium, hallucinations, lethargy, seizures, and stupor. Coma is rare and is generally a late finding occurring in severe acute poisoning or mixed overdoses.^{4,133}

Paratonia, extreme muscle rigidity, has been observed in severe salicylate poisoning pre- and postmortem, and in one case, it was even unresponsive to succinylcholine.^{80,103} Decreased ATP production, impaired glycolysis, increased lactate, and uncoupling of muscular oxidative phosphorylation likely contribute to this phenomenon. This excess neuromuscular activity may lead to rhabdomyolysis and most concerning hyperthermia that is typically a preterminal condition.^{72,83,84}

Chronic Salicylate Toxicity

Chronic salicylate poisoning most typically occurs in elderly individuals as a result of unintentional overdosing on salicylates used to treat chronic conditions such as rheumatoid arthritis and osteoarthritis^{5,29,65} (Table 39–2). Presenting signs and symptoms of chronic salicylate poisoning can be similar to those of acute toxicity and include nausea and vomiting, hearing loss and tinnitus, dyspnea and hyperventilation, tachycardia, hyperthermia, and neurologic manifestations such as confusion, delirium, agitation, hyperactivity, slurred speech, hallucinations, seizures, and coma.^{4,32,71} Although there is considerable overlap with acute salicylate poisoning, the slow, insidious onset of chronic poisoning in elderly individuals frequently causes delayed recognition of the true cause of the patient’s presentation.^{4,44,70}

TABLE 39–2. Differential Characteristics of Acute and Chronic Salicylate Poisoning

	<i>Acute</i>	<i>Chronic</i>
Age	Younger	Older
Etiology	Overdose usually intentional	Therapeutic misadventures; iatrogenic
Diagnosis	Easily recognized	Frequently unrecognized
Other diseases	None	Underlying disorders (especially chronic pain conditions)
Suicidal ideation	Typical	Atypical
Serum concentrations	Marked elevation	Intermediate elevation
Mortality	Uncommon when recognized and properly treated	More common due to delayed recognition

Typically, ill patients who have chronic salicylate poisoning may be misdiagnosed as having delirium, dementia, or encephalopathy of undetermined origin, or diseases such as sepsis (fever of unknown origin), alcoholic ketoacidosis, respiratory failure, or cardiopulmonary disease.^{4,6,20,36} Unfortunately, many of the signs and symptoms of chronic salicylate toxicity may be mistakenly attributed to the illness for which the salicylates were administered.^{20,119} Despite an extensive evaluation during a first hospitalization for ARDS, chronic salicylism was not diagnosed until a second hospitalization for the same respiratory symptoms.²² This case highlights the need to include chronic salicylism in the differential for ARDS with or without neurologic symptoms.

In a study of 73 consecutive adults hospitalized with salicylate poisoning, 27% were not correctly diagnosed for as long as 72 hours after admission.⁴ These patients manifested toxicity with standard or excessive therapeutic regimens and had significant associated diseases without a history of previous overdoses. In this group, 60% of the patients had a neurologic consultation before the diagnosis of salicylism was established. When diagnosis is delayed in elderly individuals, the morbidity and mortality associated with salicylate poisoning are high. The mortality rate was reported to be as high as 25% in the 1970s,⁴ and there are no data to suggest that survival after delayed diagnosis is substantially better today.

EVALUATION AND DIAGNOSTIC TESTING

The most commonly reported route of salicylate exposure is from the acute ingestion of aspirin, which, as mentioned earlier, has a very short serum half-life of about 15 minutes during which time it is rapidly converted to salicylate. The symptoms of toxicity are due to the systemic effects of salicylate and not the parent compound. Systemic toxicity is concerning after the following exposures: ingestions of 150 mg/kg or 6.5 g of aspirin, whichever is less; ingestion of greater than a lick or taste of oil of wintergreen (98% methyl salicylate) by children younger than 6 years of age; and more than 4 mL of oil of wintergreen by patients 6 years of age and older.²¹ These patients as well as those with significant topical exposures and signs of toxicity should be promptly evaluated for salicylate toxicity.

The initial approach to a patient suspected of salicylate toxicity should obviously include a serum salicylate concentration. But it is very important to recognize that other laboratory assays such as an ABG or VBG, electrolytes to determine anion gap, the presence of serum or urine ketones, and a lactate concentration can be critical in uncovering an unrecognized salicylate poisoning. It also may be important to evaluate renal and hepatic function because dysfunction in either will exacerbate toxicokinetic effects in patients with acute or chronic exposures.

As aspirin or other parent compounds are metabolized to salicylate, there should be a drop in serum bicarbonate,

leading to an increase in the anion gap. Elevated anion gaps are caused by increases in unmeasured anions that are primarily salicylate but also related to increases in lactic acid, ketoacids, and daily endogenous dietary acids. Volume loss from vomiting and excess metabolic energy can cause AKI, which will decrease the elimination of dietary acids.

Several studies have suggested that empiric serum salicylate concentrations are not required as part of a general toxicologic evaluation in patients with acute self-poisoning. Routine salicylate testing is likely unnecessary without a positive history of salicylate ingestion, an inability to obtain a valid history (altered mental status), or clinical features of salicylate poisoning.^{18,48,130} One retrospective study also suggested that screening for salicylism is not needed in the absence of an elevated anion gap.¹¹⁴ Although an anion gap metabolic acidosis is likely found in most cases of salicylate toxicity, severe salicylism may falsely elevate serum chloride, bringing the anion gap closer to a normal range.⁵⁹

Although it may be wise to curtail empiric testing, clinicians should likely err on the side of ordering a salicylate assay if there is any clinical concern because the morbidity and mortality are significantly increased with delays in recognition and management. Many of the signs and symptoms of salicylate toxicity are vague and may be mistakenly attributed to another illness with disastrous consequences. In the review of all salicylate deaths in Ontario, Canada, in 1983 and 1984, the author noted that in six of the 23 (26%) patients who arrived alert, no salicylate determination appears to have been made and that probably neither the diagnosis nor the severity of the salicylate poisoning was recognized.⁸⁰

Salicylate Analysis

Serum salicylate concentrations are relatively easy to obtain in most hospital laboratories today. Several methods are available for determining serum salicylate concentrations. The Trinder assay is the most popular method for the measurement of salicylate in serum by using spectrophotometric analysis. Trinder's reagent contains mercuric chloride and hydrochloric acid used to precipitate serum proteins. The measured absorbance at 540 nm of a ferric ion-salicylate complex allows for accurate determination of the serum salicylate concentration. Historically there have been several bedside urine qualitative tests (ie, mercuric chloride, ferric chloride) used to assess for the presence of salicylate. They have no clinical utility today because of poor specificity and chemical hazards and are no longer permissible under the federal Clinical Laboratory Improvement Amendments (CLIA) in the United States.

Serum salicylate concentrations are commonly reported in mg/dL in the United States, but confusion can arise because values can also be reported in mg/L and $\mu\text{g/mL}$. Analyzing and reporting salicylate concentrations as mg/L when the clinician is accustomed to receiving results as mg/dL or inadvertently reporting actual mg/L (before internal laboratory conversion) produces erroneous results.⁴⁹ These may suggest a toxic salicylate concentration in a patient whose serum salicylate concentration is actually within the therapeutic range (eg, "165 mg/L" instead of "16.5 mg/dL"). Most errors can be eliminated before initiation of aggressive therapy, such as hemodialysis (HD), by determining whether the reported salicylate concentration is consistent with the clinical presentation and ABG or VBG results and, when time permits, repeating the salicylate determination with appropriate consideration for methodology and conversion calculations.⁴⁹ Using the earlier example, a patient with a serum salicylate concentration of 165 mg/dL would undoubtedly show clinical signs of salicylate toxicity and have a profound acid-base abnormality, but a patient with a concentration of 165 mg/L would likely be asymptomatic.

It should also be noted that several clinical scenarios and xenobiotic exposures are recognized to cause false-positive or falsely elevated true salicylate concentrations. Medications that may interfere with the assay include thioridazine, promethazine, prochlorperazine, chlorpromazine, acetylcysteine, and cysteamine.⁸ Significantly falsely elevated serum salicylate concentrations are well recognized after diflunisal overdose.^{30,118} Hyperbilirubinemia can create clinically significant false-positive results in neonates and adults.^{8,13} Interestingly, hyperlipidemia can also cause significant interference and false elevation of serum salicylate concentrations.¹⁹ If there is concern for false salicylate concentrations, clinicians should contact laboratory personnel, who often have information regarding instrument-specific recognized interferences for each assay as published by the manufacturer. Several techniques may be used to determine a true salicylate concentration in the setting of a known interference. One of the most sensitive and specific assays now available is an automated immunoassay based on specific antisalicylate antiserum with fluorescence polarization immunoassay (FPIA) detection technology.⁸

Interpretation of Serum Salicylate Concentrations and Correlation with Toxicity

The recommended therapeutic concentration of salicylate is 10 to 30 mg/dL, but this varies by indication. Antiinflammatory dosing usually is advised to be on the higher end of this spectrum, but analgesic effects can be observed as low as 5 to 10 mg/dL. Values above 30 mg/dL are usually not found unless there is a supratherapeutic, acute, or chronic toxic exposure.

The correlation of serum salicylate concentrations and clinical toxicity is often poor and dependent on several factors. A concurrent arterial or venous blood pH should be determined when a serum salicylate concentration is obtained because in the presence of acidemia, more salicylic acid leaves the blood and enters the CSF and other tissues (Fig. 39-2), increasing the toxicity. A decreasing serum salicylate concentration may be difficult to interpret because it may reflect

either an increased tissue distribution with increasing toxicity or an increased clearance with decreasing toxicity. A decreasing serum salicylate concentration accompanied by a decreasing or low blood pH should be presumed to reflect a serious or worsening situation, not a benign or improving one. Patients with chronic toxicity demonstrate more significant clinical effects at lower concentrations compared with acute toxicity given the increased distribution over time into tissue compartments and specifically the CNS.

FIGURE 39–2. Rationale for alkalization. Alkalization of the plasma with respect to the tissues and alkalization of the urine with respect to plasma shifts the equilibrium to the plasma and urine and away from the tissues, including the brain. This equilibrium shift results in “ion trapping.”

Although impractical clinically, salicylate concentrations in the CSF are likely the most accurate measure of toxicity, directly correlating with death in a rat model.⁵⁴ Animals that were lethally poisoned with salicylate were comatose and died from seizures. The time to death after salicylate administration varied greatly as did the blood, muscle, and liver salicylate concentrations. However, regardless of the time of death and the concentrations in blood, muscle, or liver, all animals died with a consistent range of CSF salicylate concentrations.⁵⁴ Inhalation of CO₂ (lowering serum pH) in a rat resulted in a precipitous decrease in serum salicylate concentrations, which returned to baseline rapidly after the discontinuation of CO₂.⁵³ This suggests that the salicylate redistributed into tissue during the period of induced respiratory acidosis and reequilibrated after its correction. After administration of radiolabeled salicylate to cats, autoradiographs of the brain visually and objectively documented the profound effect that acidemia has on the distribution of salicylate into the brain.⁴⁷

Before serum assays were readily available, physicians who prescribed aspirin would advise patients to take repeated doses until tinnitus occurred and then “back off” a little to maintain this “steady state.” Tinnitus and the subsequent reversible hearing loss typically occur at serum salicylate concentrations of 20 to 45 mg/dL.^{12,15,87} This prompted investigations into whether salicylate-induced tinnitus could be used as an indicator of serum salicylate concentration and toxicity. Unfortunately, some patients with therapeutic concentrations of salicylates had tinnitus, and many with higher or toxic concentrations had no tinnitus. In a study of 94 patients with salicylate concentrations above 30 mg/dL on one or more occasions, tinnitus only correlated with serum salicylate concentrations in 30%; 55% had no tinnitus, although audiologic testing results were usually abnormal regardless of the patient’s perception of presence or absence of tinnitus.⁵⁰ Thus, although symptomatic ototoxicity may be a helpful warning sign of salicylate toxicity when present, it is too nonspecific and too insensitive to serve as an indicator of serum salicylate concentrations.

MANAGEMENT

The management of patients with salicylate toxicity is aimed at supporting vital signs and organ function, preventing or limiting ongoing exposure from the gut or skin, and enhancing elimination of salicylate that has already entered the systemic circulation. It is imperative to understand that there is no true antidote for salicylate toxicity; no xenobiotic can combat the clinical toxicity demonstrated in consequential exposures. HD, as discussed later, aims to remove salicylate from the tissues but may not correct severe organ toxicity such as ARDS or cerebral edema and can therefore not guarantee survival after severe toxicity occurs.^{40,82} Rather, all therapies are better at preventing tissue injury than treating it.

It is imperative to understand that the primary toxicity of salicylate is on the CNS, and the amount of salicylate in the brain is a function of pH with acidemia enhancing CNS penetration of the drug. Management strategies strive to create concentration gradients and pH conditions that favor exit of salicylate from the CNS and other tissues and enhanced renal elimination.

Gastrointestinal Decontamination and Use of Activated Charcoal and Catharsis

The use of orogastric lavage and activated charcoal (AC) is discussed in [Chap. 8](#) and Antidotes in Depth: A1. Their effects on the absorption and elimination of salicylates have been extensively studied. In vitro studies suggest that each gram of AC can adsorb approximately 550 mg of salicylic acid.^{75,89} In humans, AC reduces the absorption of therapeutic doses of aspirin by 50% to 80%, effectively adsorbing aspirin released from enteric-coated and sustained-release preparations in addition to immediate-release tablets.⁷⁵ Presumably, the sooner AC is given after salicylate ingestion, the more effective it will be in reducing absorption. A 10:1 ratio of AC to ingested salicylate appears to result in maximal efficacy but is often impractical given the fact that ingestions of salicylate often reach 20- to 30-g amounts or more. Although peak serum concentrations are markedly decreased from predicted concentrations, aspirin desorption from the aspirin-AC complex in the alkaline milieu of the small bowel may diminish the impact of AC on total absorption.^{42,79,89} The addition of a cathartic to the initial dose of AC has been questioned and largely abandoned for most xenobiotics, but a benefit of adding sorbitol to AC in preventing salicylate absorption was demonstrated in one study.⁶⁶ A single dose may still therefore be acceptable.

Repetitive or multiple-dose AC (MDAC) is necessary to achieve desired ratios of activated charcoal to salicylate (and probably limits desorption), which may reduce the concentration of initially absorbed salicylate to only 15% to 20%.⁴² MDAC appears to increase the elimination of unabsorbed salicylates over that achieved by single-dose AC.^{7,55} Thus, the use of MDAC to decrease GI absorption of salicylates is warranted, barring contraindications particularly if a pharmacobezoar or extended-release preparation is suspected (Antidotes in Depth: A1).

The value of MDAC in enhancing salicylate elimination through GI dialysis is controversial and is not generally warranted.^{3,60} In one volunteer study of a 2800-mg dose of aspirin followed by 25 g of AC at 4, 6, 8, and 10 hours after ingestion, the total amount of salicylate excreted from the body increased by 9% to 18% but was not considered statistically significant.⁶⁷ The efficacy is likely greater in an overdose situation, when more unbound salicylate is available because of decreased protein binding. However, in another study of the effects of MDAC on the clearance of high-dose intravenous (IV) aspirin in a porcine model, MDAC did not enhance the clearance of salicylates under conditions when the venous bicarbonate was kept at 15 mEq/L or less and urine pH kept at 7.5 or less.⁶⁰ In contrast to the findings of both of these studies, two children with salicylate overdoses were successfully treated with MDAC given every 4 hours for 36 hours.¹²⁶ Overall, extensive use of MDAC is currently discouraged, but the administration of two to four properly timed doses is reasonable. The administration of AC or MDAC must be balanced against risks of vomiting and aspiration, especially in patients with altered mental status and unprotected airways ([Chap. 8](#)).

Theoretical support may be found for the use of whole-bowel irrigation (WBI) with polyethylene glycol electrolyte lavage solution (PEG-ELS) in addition to AC to reduce absorption, particularly for enteric-coated aspirin preparations.¹²¹ However, because the addition of WBI to MDAC does not increase the clearance of absorbed salicylate in an experimental model,⁷⁹ it is not routinely recommended.

Fluid Replacement

There is a need to differentiate between restoration of fluid and electrolyte balance in salicylate-poisoned patients and increasing the fluid load presented to the kidneys in an attempt to achieve “forced diuresis.” Fluid losses in patients with salicylate poisoning are prominent, especially in children, and can be attributed to hyperventilation, vomiting, fever, a hypermetabolic state, cathartic administration, and perspiration.¹²⁰ The kidneys also respond to salicylate poisoning by excreting an increased solute load, including large quantities of bicarbonate, sodium, potassium, and organic acids.⁵ For all of these reasons, the patient’s volume status must be adequately assessed and corrected if necessary along with any glucose and electrolyte abnormalities. As in other cases, accurate management of volume status in poisoned patients may require invasive or noninvasive monitoring of central venous pressures, especially in patients with cardiac disease, ARDS, or AKI.

Increasing fluids beyond restoration of fluid balance to achieve forced diuresis is a practice that was inappropriately promoted in the past. Although forced diuresis theoretically increases renal tubular flow and reduces the urine tubular cell diffusion gradient for reabsorption, renal excretion of salicylate depends much more on urine pH than on flow rate, and use of forced diuresis alone is not effective regardless of whether diuretics, osmotic agents, or large fluid volumes are used to achieve the diuresis.⁹⁷ Although renal salicylate clearance varies in direct proportion to flow rate, its relation to pH is logarithmic.^{62,70} In summary, although fluid imbalance must be corrected, forced diuresis does little more than oral fluids to enhance elimination over a 24-hour period⁹⁷ and subjects the patient to the hazards of fluid overload.

Serum and Urine Alkalinization

The cornerstone of the management of patients with salicylate toxicity is to shift salicylate out of the brain and tissues into the serum, where elimination through the kidneys can then occur. Alkalinization of the serum with respect to the tissues and alkalinization of the urine with respect to the serum accomplishes this goal by facilitating the movement and “ion trapping” of salicylate into the serum and the urine (Fig. 39–2). Alkalinization of the serum by a substance that does not easily cross the blood–brain barrier such as intravenously administered sodium bicarbonate reduces the fraction of salicylate in the nonionized form and increases the pH gradient with the CSF. This both prevents entry and helps remove salicylate from the CNS.^{47,52–54,119}

Alkalinization with IV sodium bicarbonate should be considered for all symptomatic patients whose serum salicylate concentrations exceed the therapeutic range and for clinically suspected cases of salicylism until a salicylate concentration and simultaneously obtained blood pH are available to guide treatment. Patients on therapeutic regimens of salicylates who feel well with salicylate concentrations of 30 to 40 mg/dL and who do not manifest toxicity do not require intervention.

Alkalinization may be achieved with a bolus of 1 to 2 mEq/kg of sodium bicarbonate IV followed by an infusion of 3 ampules of sodium bicarbonate (132 mEq) in 1 L of 5% dextrose in water (D₅W), administered at 1.5 to 2.0 times the maintenance fluid range. Urine pH should be maintained at 7.5 to 8.0, and hypokalemia must be corrected (see later discussion) to achieve maximum urinary alkalinization. Volume load should remain modest while previous losses are replenished (Antidotes in Depth: A5).

Oral bicarbonate administration should never be substituted for IV bicarbonate to achieve alkalinization because the oral route may increase salicylate absorption from the GI tract by enhancing dissolution. Hyperventilation alone should not be relied upon, and intravenous sodium bicarbonate should be used for alkalinization.

Urine Alkalinization

Because salicylic acid is a weak acid (pK_a 3.0), it is ionized in an alkaline milieu and theoretically can be “trapped” there. This occurs because there is no specific uptake mechanism in the kidney for salicylate ion, and passive reabsorption of a charged molecule is very limited. Thus, alkalinization of the urine (defined as $pH \geq 7.5$) with sodium bicarbonate results in enhanced excretion of the ionized salicylate ion.

Alkalinization of the urine should be considered as a first-line treatment for patients with moderately severe salicylate poisoning who do not meet the criteria for HD.^{99,123} It should also be administered to salicylate-poisoned patients who require HD while preparations are being made to perform HD. Although salicylic acid is almost completely ionized within physiologic pH limits, small changes in pH obtained by alkalinization may have substantial changes in the relative amount of salicylate in the charged form.

Regardless of the reason for the change in serum pH, renal excretion of salicylate is very dependent on urinary pH.^{62,97,127} Alkalinization increases free salicylate secretion from the proximal tubule but does not affect renal elimination of salicylate conjugates. Alkalinizing the urine from a pH of 5 to 8 logarithmically increased renal salicylate clearance from 1.3 to 100 mL/min^{62,86} (Fig. 39–3). Assuming an overdose V_d of 0.5 L/kg, this increased clearance would decrease salicylate half-life from 310 to 4 hours. However, in reality alkalinizing the urine from a pH of 5 to 8 has a more modest effect on serum salicylate clearance.⁹⁷

FIGURE 39–3. The relationship between urine pH and urine salicylate clearance. This curve was adapted from a

logarithmic relationship determined by Kallen in patients with salicylate poisoning. It illustrates the need to substantially increase urine pH above 7 to impact elimination.

Although the administration of acetazolamide, a noncompetitive carbonic anhydrase inhibitor, results in the formation of bicarbonate-rich alkaline urine, it also causes a metabolic acidosis and acidemia.^{41,52,53} This latter effect of acetazolamide is usually self-limited and mild but nevertheless increases the concentration of freely diffusible nonionized molecules of salicylic acid, thereby increasing the Vd and most probably enhancing the penetrance of salicylate into the CNS.^{53,73}

Hypokalemia is a common complication of salicylate poisoning and sodium bicarbonate therapy and can prevent urinary alkalization unless corrected. In the presence of hypokalemia, the renal tubules reabsorb potassium ions in exchange for hydrogen ions, preventing urinary alkalization. If urinary alkalization cannot be achieved easily, hypokalemia, excretion of organic acids, and salt and water depletion should be considered possible reasons. Calcium concentrations should be monitored because decreases in both ionized²⁹ and total serum calcium⁴³ are also complications of bicarbonate therapy.

Glucose Supplementation

As discussed earlier, salicylate poisoning may significantly alter glucose metabolism, transport, and relative requirements. Clinically, this is relevant in that the presence of a normal serum glucose concentration may not be reflective of a normal CSF glucose concentration. It is suggested that the neurotoxicity of salicylism may be partly caused by this hypoglycorrhachia. Dextrose administration alone has reversed acute delirium associated with salicylate toxicity.^{23,69} It is therefore wise to liberally administer dextrose to all patients with altered mental status in salicylate toxicity regardless of their serum glucose concentration. A bolus of 0.5 to 1 g/kg of dextrose with additional or even continuous infusion should be considered in patients being treated for severe salicylate toxicity.

Extracorporeal Removal

Extracorporeal measures are indicated if the patient has severe signs or symptoms, a very high serum salicylate concentration regardless of clinical findings, severe fluid or electrolyte disturbances, cerebral edema, or ARDS or is unable to eliminate the salicylates because of AKI (Table 39–3). It should also be considered when a patient cannot tolerate the increased solute load that results from alkalization or large-volume infusions necessary. Failure to tolerate such therapy can be anticipated if the patient has initial symptoms that are consistent with severe salicylate toxicity or has a history congestive heart failure or chronic kidney disease.

TABLE 39–3. Indications for Hemodialysis in Salicylate Poisoned Patients

Kidney failure
Congestive heart failure (relative)
Acute Respiratory Distress Syndrome
Persistent Central Nervous System disturbances
Progressive deterioration in vital signs
Severe acid–base or electrolyte imbalance despite appropriate treatment
Hepatic compromise with coagulopathy
Salicylate concentration (acute) >90 mg/dL (in the absence of the above)
Hemodialysis for patients with chronic poisoning is indicated for those with concerning symptoms regardless of salicylate concentrations

In most instances, HD is the extracorporeal technique of choice, not only to clear the salicylate but also to rapidly correct fluid, electrolyte, and acid–base disorders that will not be corrected by hemoperfusion (HP) alone. The combination of HD and HP in series is feasible and theoretically may be useful for treating patients with severe or mixed overdoses,²⁷ but it is rarely used. A rapid reduction of serum salicylate concentrations in severely poisoned patients has been described with the use of continuous renal replacement therapy, a technique that may be valuable for patients who are too unstable to undergo HD or when HD is unavailable¹³² (Chap. 10). There is only one published clinical experience with sustained low-efficiency dialysis (SLED) for salicylate toxicity, which demonstrated similar clearance rates to other

continuous extracorporeal therapies.⁷⁶ Its role still requires further investigation.⁷⁶

While the patient is awaiting HD, alkalization of serum and urine should be aggressively achieved with sodium bicarbonate therapy. During HD, it is unnecessary to continue bicarbonate therapy because it will be provided by HD. It is prudent to reinstitute bicarbonate therapy after HD has been completed, especially if patients are still symptomatic or serum salicylate concentrations are pending.

Nephrology consultation should be sought early and liberally to anticipate and prevent avoidable morbidity and mortality. Despite the well-recognized benefit of extracorporeal removal of salicylates in severe toxicity, delays in initiating HD remain a potentially preventable cause of death despite repeated calls over many years for prompt HD for patients with salicylate poisoning.⁴⁰ The initiation of HD should not be considered definitive treatment because patients may still have a significant GI burden of salicylate, resulting in continued absorption, and even with early and multiple runs of HD, patients may still succumb to this poisoning.⁸²

Chemical Sedation, Intubation, and Mechanical Ventilation Risks

Salicylate-poisoned patients have a significantly increased minute ventilation rate brought about by both tachypnea and hyperpnea, often exceeding 20 to 30 L/min. Any decrease in minute ventilation increases the PCO₂ and decreases the pH. This shifts salicylate into the CNS, exacerbating toxicity. Thus, extreme caution must be used when considering chemical sedation, intubation, and initiating mechanical ventilation.

Although induced hyperventilation may effectively increase the blood pH in certain patients, endotracheal intubation followed by assisted ventilation of a salicylate-poisoned patient poses particular risks if it is not meticulously performed. Although early endotracheal intubation to maintain hyperventilation may aid in the management of patients whose respiratory efforts are faltering, health care providers must maintain appropriate hypocarbia through hyperventilation. Ventilator settings that result in an increase in the patient's PCO₂ relative to premechanical ventilation will produce relative respiratory acidosis even if serum pH remains in the alkalemic range.

In a search of a poison center database of patients with salicylate poisoning between 2001 and 2007, seven patients were identified with salicylate concentrations above 50 mg/dL who had both premechanical ventilation and postmechanical ventilation data. All seven had postmechanical ventilation pH values below 7.4, and five of the six for whom recorded PCO₂ values were available had postmechanical ventilation PCO₂ values above 50 mm Hg, suggesting substantial underventilation. Two of the seven patients died after intubation, and one sustained neurologic injury. Inadequate mechanical ventilation of patients with salicylate poisoning was associated with respiratory acidosis, a decrease in the serum pH, and an abrupt clinical deterioration.¹¹⁶ Even when achieved, however, respiratory alkalosis sustained by hyperventilation (assisted or unassisted) alone should never be considered a substitute for use of either sodium bicarbonate (to achieve both alkalemia and alkaluria) or HD (when indicated).

If chemical sedation is required, although there is no clear choice of preferred sedative, the goals are to minimize respiratory depression and use the minimum amount required for desired sedation. If intubation is deemed necessary, which it often may be in situations of severe toxicity or multidrug ingestions, the following steps should be taken to optimize before, during, and after intubation conditions. The goal should be to maintain or exceed minute ventilation rates that were present before intubation. Before intubation, an attempt should be made to optimize serum alkalization by administering a 2-mEq/kg bolus of sodium bicarbonate. Preparations should be made to minimize the period of time the patient will spend with apnea or decreased ventilation by considering an awake intubation. The provider most experienced in intubation should be present as well as any adjunct materials to increase first-pass success. An intensivist, respiratory technician, or other mechanical ventilator expert should be consulted to help match preintubation minute ventilation. After mechanical ventilation has begun, frequent blood gas monitoring should be obtained and ventilator settings adjusted as needed. An emergent nephrology consult is indicated for HD if not previously obtained.¹¹⁶ One recent report suggested the use of ketamine for awake intubation, thereby minimizing the hypoventilation associated with rapid-sequence intubation.³⁸

Serum Salicylate Concentration and pH Monitoring

Careful observation of the patient, correlation of the serum salicylate concentrations with blood pH, and repeat determinations of serum salicylate concentrations every 2 to 4 hours are essential until the patient is clinically improving and has a low serum salicylate concentration in the presence of a normal or high blood pH. In all cases, after a presumed peak serum salicylate concentration has been reached, at least one additional serum concentration should be obtained several hours later. Analyses should be obtained more frequently in managing seriously ill patients to assess the efficacy of treatment and the possible need for HD.

Pediatric Considerations

The predominant primary respiratory alkalosis that initially characterizes salicylate poisoning in adults may not occur in young children.^{45,119} This likely results from the limited ventilatory reserve of small children that prevents the same degree

of sustained hyperpnea as occurs in adults. The typical acidemia noted in seriously poisoned children led some investigators in the past to incorrectly suggest that pediatric salicylate poisoning produces only metabolic acidosis. Although after a significant salicylate exposure, some children present with a mixed acid–base disturbance and a normal or high pH, most present with acidemia,⁴⁵ suggesting the need for more urgent intervention because the protective effect of alkalemia on CNS penetration of salicylate is already lost. Although not routinely recommended, exchange transfusion may effectively remove large quantities of salicylate in infants too small to undergo emergent HD without extensive delays.⁷⁷

Pregnancy

Considered a rare event, salicylate poisoning during pregnancy poses a particular hazard to fetuses because of the acid–base and hematologic characteristics of fetuses and placental circulation. Salicylates cross the placenta and are present in higher concentrations in a fetus than in the mother. The respiratory stimulation that occurs in the mother after toxic exposures does not occur in the fetus, which has a decreased capacity to buffer acid. The ability of a fetus to metabolize and excrete salicylates is also less than in the mother. In addition to its toxic effects on the mother, including coagulation abnormalities, acid–base disturbances, tachypnea, and hypoglycemia, repeated exposure to salicylates late in gestation displaces bilirubin from protein binding sites in the fetus, causing kernicterus.

A case report described fetal demise in a woman who claimed to ingest 50 aspirin tablets per day for several weeks during the third trimester of pregnancy. This raises concerns that a fetus is at greater risk from salicylate exposures than is the mother. Emergent delivery of near-term fetuses of salicylate-poisoned mothers should be considered on a case-by-case basis⁹¹ (Chap. 31).

SUMMARY

- The clinical presentation of a patient with a salicylate overdose may be characterized by an early onset of nausea, vomiting, abdominal pain, tinnitus, and lethargy.
- The combination of a primary respiratory alkalosis and a primary metabolic acidosis with net alkalemia constitutes the classic acid–base abnormality of salicylate poisoning in the adult.
- Initial efforts in managing patients with salicylate poisoning include restoration of intravascular volume, the use of AC to limit absorption, and urinary alkalization to enhance renal elimination of salicylate.
- HD is indicated in patients with significantly elevated salicylate concentrations, altered mental status, ARDS, and or AKI.
- It is essential to maintain alkalemia to prevent CNS penetration of salicylate. As such, sedation and mechanical ventilation can be rapidly lethal, if they impair minute ventilation, causing rises in PCO₂ and a fall in pH.

A5 ANTIDOTES IN DEPTH

Sodium Bicarbonate

Paul M. Wax

INTRODUCTION

Sodium bicarbonate is a nonspecific antidote that is effective in the treatment of a variety of poisonings by means of a number of distinct mechanisms ([Table A5–1](#)). However, the support for its use in these settings is predominantly based on animal evidence, case reports, and consensus.¹¹ It is most commonly used to treat patients with cyclic antidepressant (CA) and salicylate poisonings. Sodium bicarbonate also has a role in the treatment of phenobarbital, chlorpropamide, and chlorophenoxy herbicide poisonings and wide-complex tachydysrhythmias induced by Na⁺ channel blocking xenobiotics such as type IA and IC antidysrhythmics and cocaine. Correcting the life-threatening acidemia induced by methanol and ethylene glycol metabolism and enhancing formate elimination are other important indications for sodium bicarbonate. The use of sodium bicarbonate in the treatment of rhabdomyolysis, metabolic acidosis with elevated lactate, cardiac resuscitation, and diabetic ketoacidosis is controversial and not addressed in this Antidote in Depth.^{3,6,17,57,113,114}

TABLE A5–1. Sodium Bicarbonate: Mechanisms, Site of Action, and Uses in Toxicology

<i>Mechanism</i>	<i>Site of Action</i>	<i>Uses</i>
Alters interaction between xenobiotic and Na ⁺ channel	Heart	β-Adrenergic antagonists with MSE Amantadine Carbamazepine Chloroquine Citalopram Cocaine Cyclic antidepressants Dimenhydrinate Diphenhydramine Disopyramide Encainide Flecainide Fluoxetine Hydroxychloroquine Lamotrigine Mesoridazine Orphenadrine Procainamide Propafenone Propoxyphene Quinidine Quinine Taxus containing species Thioridazine Venlafaxine
Alters xenobiotic ionization leads to altered tissue distribution	Brain	Formic acid Phenobarbital Salicylates
Alters xenobiotic ionization leading to enhanced xenobiotic elimination	Kidneys	Chlorophenoxy herbicides Chlorpropamide Diflunisal Fluoride Formic acid Methotrexate Phenobarbital Salicylates Uranium
Corrects life threatening acidemia	Metabolic	Cyanide Ethylene glycol Metformin Methanol
Increases xenobiotic solubility	Kidneys	DAMPA Methotrexate
Neutralization	Lungs	Chlorine gas, HCl
Maintenance of chelator effect	Kidneys	Dimercaprol (BAL)–metal
Reduces free radical formation	Kidneys	Contrast media

BAL = British anti-Lewisite; DAMPA = 4-amino-4-deoxy-10-methylpteroic acid; MSE = membrane-stabilizing effect: acebutolol, betaxolol, carvedilol, metoprolol, oxprenolol, propranolol.

PHARMACOLOGY

Sodium bicarbonate has a molecular weight of 84 Da. It is supplied in solution at approximately pH 8.0 (pH limits range from 7.0 to 8.5). The onset of action of intravenous (IV) sodium bicarbonate is within 15 minutes with a duration of action of 1 to 2 hours. Sodium bicarbonate increases plasma bicarbonate and buffers excess hydrogen ion.³² In normal individuals, the distribution volume for bicarbonate salts is approximately twice the extracellular fluid (ECF) volume.^{43,105} The apparent bicarbonate space (ABS) proportionally increases in severe acidemia, leading to higher bicarbonate requirements.³⁷ Canine studies demonstrated that this effect is not due to the acidemia per se, but due to the tight correlation of extracellular bicarbonate concentrations with the ABS.¹ Whether acidemic or alkalemic, low bicarbonate concentrations increase the apparent space of distribution in a highly dynamic manner.¹ Human studies, in which the ABS is described by the equation, $ABS = (0.36 + 2.44/[HCO_3^-]) \times \text{body weight (kg)}$, appear to support this concept.⁹²

ROLE IN MYOCARDIAL SODIUM CHANNEL TOXINS

The most important role of sodium bicarbonate in toxicology is the ability to reverse potentially fatal cardiotoxic effects of myocardial Na^+ channel blockers such as CAs and other type IA and IC antidysrhythmics.¹⁸ Its mechanism of action in these cases appears to result from both an increase in $[Na^+]$ and a change in the proportion of the Na^+ channel blocker ionized, resulting in an altered distribution away from its channel. Use of sodium bicarbonate for myocardial Na^+ channel blocker overdose developed as an extension of sodium lactate use in the treatment of patients with toxicity from type IA antidysrhythmics. Noting similarities in electrocardiographic (ECG) findings between hyperkalemia and quinidine toxicity (ie, QRS widening), investigators in the 1950s began to use sodium lactate (which is rapidly metabolized in the liver to sodium bicarbonate) to treat quinidine toxicity.^{5,10,117} In a canine model, quinidine-induced ECG changes and hypotension were consistently reversed by infusion of sodium lactate.⁹ Clinical experience confirmed this benefit.¹⁰ Similar efficacy in the treatment of patients with procainamide cardiotoxicity was also reported.¹¹⁷

The introduction of CAs during the 1960s also yielded reports of conduction disturbances, dysrhythmias, and hypotension occurring in overdose. Extending the use of sodium lactate for the type I antidysrhythmics to CA poisoning, uncontrolled observations in the 1970s showed a decrease in mortality rate from 15% to less than 3%.³⁸ In 1976, sodium bicarbonate was reported successful in a pediatric series of CA-induced dysrhythmias.²¹ In this series, nine of 12 children who had developed multifocal premature ventricular contractions (PVCs), ventricular tachycardia, or heart block reverted to normal sinus rhythm with sodium bicarbonate therapy alone. An early canine experiment of amitriptyline-poisoning demonstrated resolution of dysrhythmias upon blood alkalization to a pH above 7.40.²¹ Other methods of alkalization, including hyperventilation and administration of the nonsodium buffer tris (hydroxymethyl) aminomethane (THAM), were also effective in reversing the dysrhythmias.^{20,55}

An improved understanding of the mechanism and utility of sodium bicarbonate came from a series of animal experiments during the 1980s. In amitriptyline-poisoned dogs, sodium bicarbonate reversed conduction disturbances and ventricular dysrhythmias and suppressed ventricular ectopy.⁷⁵ When comparing sodium bicarbonate, respiratory alkalemia (hyperventilation), hypertonic sodium chloride, and lidocaine, sodium bicarbonate, and hyperventilation proved most efficacious in reversing ventricular dysrhythmias and narrowing QRS prolongation. Although lidocaine transiently antagonized dysrhythmias, this antagonism was demonstrable only at nearly toxic lidocaine concentrations and was associated with hypotension. Furthermore, prophylactic alkalization protected against the development of dysrhythmias in a pH-dependent manner.

In desipramine-poisoned rats, the isolated use of either sodium chloride or sodium bicarbonate was effective in decreasing QRS duration.⁸³ Both sodium bicarbonate and hypertonic sodium chloride also increased mean arterial pressure, but hyperventilation or direct intravascular volume repletion with mannitol did not. In further studies both in vivo and on isolated cardiac tissue, alkalization and increased sodium concentration improved CA effects on cardiac conduction.^{97,98} Although respiratory alkalemia and hypertonic sodium chloride each independently improved conduction velocity, this effect was greatest when sodium bicarbonate was administered.

Another study on amitriptyline-poisoned rats demonstrated that treatment with sodium bicarbonate was associated with shorter QRS interval, longer duration of sinus rhythm, and increased survival rates.⁵⁶ Sodium bicarbonate seems to work independently of initial blood pH. Animal studies show that cardiac conduction improves after treatment with sodium bicarbonate or sodium chloride in both normal and acidemic animals.⁸³ Clinically, CA-poisoned patients who were already alkalemic responded to repeat doses of sodium bicarbonate.⁷²

Although several authors suggest that the efficacy of sodium bicarbonate is modulated via a pH-dependent change in plasma protein binding that decreases the proportion of free drug,^{20,62} further study failed to support this hypothesis.⁸⁶ The administration of large doses of a binding protein α_1 -acid glycoprotein (AAG) (to which CAs show significant affinity) to desipramine poisoned rats only minimally decreased cardiotoxicity. Although the addition of AAG increased the

concentrations of total desipramine and protein-bound desipramine in the serum, the concentration of active free desipramine did not decline significantly. A redistribution of CA from peripheral sites may have prevented lowering of free desipramine concentration. The persistence of other CA-associated toxicities, antimuscarinic effects and seizures, also argues against changes in protein-binding modulating toxicity. In vitro studies performed in plasma protein-free bath further substantiate sodium bicarbonate's efficacy independent of plasma protein binding.⁹⁸

Sodium bicarbonate has a crucial antidotal role in myocardial Na^+ channel blocker poisoning by increasing the number of open Na^+ channels, thereby partially reversing fast Na^+ channel blockade. This decreases QRS prolongation and reduces life-threatening cardiovascular toxicity such as ventricular dysrhythmias and hypotension.^{75,83,98} The animal evidence supports two distinct and additive mechanisms for this effect: a pH-dependent effect and a sodium-dependent effect. The pH-dependent effect increases the fraction of the more freely diffusible nonionized xenobiotic. Both the ionized xenobiotic and the nonionized forms are able to bind to the Na^+ channel, but assuming myocardial Na^+ channel blockers act like local anesthetics, it is estimated that 90% of the block results from the ionized form. By increasing the nonionized fraction, less xenobiotic is available to bind to the Na^+ channel binding site (Fig. A5–1). The sodium-dependent effect increases the availability of Na^+ ions to pass through the open channels. Decreased ionization should not significantly decrease the rate of CA elimination because of the small contribution of renal pathways to overall CA elimination (<5%).

FIGURE A5–1. Blockade occurs by an ionized drug because the channel is a water (lipophobic) environment (left). As the drug becomes nonionized, it becomes more lipophilic and moves into the lipid bilayer of the membrane and away from the channel (right).

Although many anecdotal accounts support the efficacy of sodium bicarbonate in treating CA cardiotoxicity in humans,⁴⁷ these reports are uncontrolled observations; controlled studies are unavailable. In one of the largest retrospective observational studies involving 91 patients who received sodium bicarbonate after CA overdose, QRS prolongation corrected in 39 of 49 patients who had QRS durations above 120 msec, and hypotension corrected within 1 hour in 20 of 21 patients who had systolic blood pressures below 90 mm Hg.⁴⁸ Use of sodium bicarbonate was not associated with any complications in this study.

Prospective validation of treatment criteria for use of sodium bicarbonate after CA overdose has not been performed. Common indications are conduction delays (as manifested by QRS above 100 msec or right bundle branch block), wide-complex tachydysrhythmias, and hypotension.⁶³ Because studies demonstrate a critical threshold QRS duration (≥ 160 msec) at which ventricular dysrhythmias significantly increase in propensity,¹⁴ it seems reasonable that narrowing the QRS interval through use of sodium bicarbonate or hyperventilation may prophylactically prevent against development of dysrhythmias. Practice patterns vary considerably with regard to the use of sodium bicarbonate when the QRS interval is below 160 msec.¹⁰² Although sodium bicarbonate has no proven efficacy in either the treatment or prophylaxis of tricyclic antidepressant-induced seizures, seizures often produce acidemia, which rapidly increases the risks of conduction disturbances and ventricular dysrhythmias.¹¹¹ Administering sodium bicarbonate when the QRS duration is 100 msec or greater may establish a theoretical margin of safety in the event the patient suddenly deteriorates, without adding significant demonstrable risk. When the QRS duration is below 100 msec, given the minimal risk of seizures or dysrhythmias, prophylactic sodium bicarbonate administration is not indicated.¹⁰³ In patients exhibiting a Brugada ECG pattern (right bundle branch block with downsloping ST segment elevation in V1–V3) and QRS widening after CA ingestion, sodium bicarbonate administration may narrow the QRS without reversing the Brugada pattern⁷ (Chap. 16).

Because cardiotoxicity may worsen during the first few hours after ingestion, sodium bicarbonate therapy should be initiated immediately if the QRS interval is greater than 100 msec. Because CA-induced hypotension responds to sodium bicarbonate, hypotension should also prompt sodium bicarbonate therapy. However, no evidence supports a role for sodium bicarbonate in CA-poisoned patients who present with altered mental status or seizures without QRS widening or hypotension.

Because the potential benefits of alkalization in CA overdose usually outweigh the risks, sodium bicarbonate should

be administered regardless of whether the patient has an acidemic or normal pH.

The time to resolution of conduction abnormalities during continuous bicarbonate infusion varies significantly, ranging from several hours to several days.^{64,103} In a case of poisoning from modified-release amitriptyline, sodium bicarbonate was required on multiple occasions over 110 hours after the initial ingestion to reverse ongoing Na⁺ channel conduction disturbances.⁷⁷ Sodium bicarbonate infusion usually is discontinued upon hemodynamic improvement and resolution of cardiac conduction abnormalities and altered mental status, although controlled data supporting such an approach are lacking.

Sodium bicarbonate is useful in treating patients with cardiotoxicity from other myocardial Na⁺ channel blockers that present with widened QRS complexes, dysrhythmias, and hypotension. Isolated case reports provide the bulk of the evidence in these situations. The utility of sodium bicarbonate in treating patients with type IA and IC antidysrhythmics, diphenhydramine, propoxyphene, quinine, and others has been demonstrated.^{13,28,29,95,104,110,117}

Use of sodium bicarbonate in the treatment of patients with overdoses of amantadine, a xenobiotic with multiple myocardial channel effects has been suggested, but concurrent hypokalemia may limit its use.¹⁰⁰ Although the usefulness of sodium bicarbonate in reversing QRS prolongation, occasionally observed during fluoxetine and citalopram overdose has been reported,^{22,31,40} Na⁺ channel disturbances are uncommon in most cases of selective serotonin reuptake inhibitor (SSRI) overdose, and routine use of alkalization therapy in this setting is unwarranted and might risk worsening QT effects by promoting hypokalemia. Sodium bicarbonate may help in the management of patients with other ingestions associated with type IA-like cardiac conduction abnormalities and dysrhythmias, such as carbamazepine, lamotrigine, and the phenothiazines thioridazine and mesoridazine, but documentation of benefit is limited to case reports.⁴⁴ Although sodium bicarbonate efficacy in the treatment of *Taxus* spp induced wide-complex dysrhythmias is reported, an animal study failed to detect any benefit.^{87,94} Bupropion's reduction of cardiac intercellular coupling (ie, inhibition of gap junction communication), as opposed to Na⁺ channel blockade,²⁴ may explain the reported lack of efficacy of sodium bicarbonate in reversing QRS prolongation in bupropion poisoning.¹¹⁹

Cocaine, a local anesthetic with membrane-stabilizing properties resembling other type I antidysrhythmics, may cause similar conduction disturbances. In several canine models of cocaine toxicity, sodium bicarbonate successfully reversed cocaine-induced QRS prolongation^{8,81} and improved myocardial function.¹²⁰ Of interest, sodium loading by itself failed to produce a benefit. Similar findings were demonstrated in cocaine-treated guinea pig hearts.¹²¹ Patients with cocaine-induced cardiotoxicity responded to treatment with sodium bicarbonate.^{54,79,116} In many of these cases, simultaneous treatment with sedation, active cooling, and hyperventilation confounds the interpretation of sodium bicarbonate's benefit.

ROLE IN ALTERING DISTRIBUTION AND ENHANCING ELIMINATION

Salicylates

Although there is no known specific antidote, judicious use of sodium bicarbonate is an essential treatment for salicylate toxicity. Through its ability to alter the concentration gradient of the ionized and nonionized fractions of salicylates, sodium bicarbonate is useful in decreasing tissue (eg, brain) concentrations of salicylates and enhancing urinary elimination of salicylates.⁹⁰ This therapy may limit the need for more invasive treatment modalities, such as hemodialysis.

Salicylate is a weak acid with a pK_a of 3.0. As pH increases, the ionized proportion increases. Because of the presence of polar groups, ionized molecules penetrate lipid-soluble membranes less efficiently than do nonionized molecules. Consequently, when the ionized forms predominate, weak acids such as salicylates may accumulate in an alkaline milieu, such as an alkaline urine.^{69,107}

Although alkalinizing the urine to increase salicylate elimination is an important intervention in the treatment of patients with salicylate poisoning, increasing the serum pH in patients with severe salicylism may prove even more consequential by protecting the brain from a lethal central nervous system (CNS) salicylate burden. In these patients, using sodium bicarbonate to “trap” salicylate in the blood (ie, keeping it out of the brain) may prevent clinical deterioration of salicylate-poisoned patients. Salicylate lethality is directly related to primary CNS dysfunction, which, in turn, corresponds to a “critical brain salicylate concentration.”⁴⁶ At physiologic pH, at which a very small proportion of the salicylate is in the nonionized form, a small change in pH is associated with a significant change in amount of nonionized molecules. For example, whereas at a pH of 7.4, 0.004% of the salicylate molecules are in the nonionized form, at a pH of 7.2, 0.008%, of the salicylate is in the nonionized form. In experimental models, lowering the blood pH produces a shift of salicylate into the tissues.²³ Hence, acidemia in patients with significant salicylate poisonings can be devastating. In salicylate-poisoned rats, increasing the blood pH with sodium bicarbonate produced a shift in salicylate out of the tissues and into the blood.⁴⁵ This change in salicylate distribution did not result from enhanced urinary excretion because occlusion of the renal pedicles failed to alter these results.

Enhancing the elimination of salicylate by trapping ionized salicylate in the urine is also beneficial. Salicylate

elimination at therapeutic concentrations is predominantly first-order hepatic metabolism. At these low concentrations, without alkalization, only approximately 10% to 20% of salicylate is eliminated unchanged in the urine. With increasing concentrations, enzyme saturation occurs (Michaelis-Menten kinetics); thus, a larger percentage of elimination occurs as unchanged free salicylate. Under these conditions, in an alkaline urine, urinary excretion of free salicylate becomes even more significant, accounting for 60% to 85% of total elimination.^{41,91} The relationship between salicylate clearance and urine pH $\{\log(\text{salicylate clearance}) = [(0.52 \times \text{pH}) - 2.1]\}$ ⁵³ would suggest that increasing urine pH from 5.0 to 8.0 could increase the amount of salicylate cleared by almost 40-fold.

The exact mechanism of pH-dependent salicylate elimination has generated controversy. The pH-dependent increase in urinary elimination initially was ascribed to “ion trapping,” which is the filtering of both ionized and nonionized salicylate while reabsorbing only the nonionized salicylate.¹⁰¹ However, limiting reabsorption of the ionizable fraction of filtered salicylate cannot be the primary mechanism responsible for enhanced elimination produced by sodium bicarbonate.⁶⁵ Because the quantitative difference between the percentage of molecules trapped in the ionized form at a pH of 5.0 (99% ionized) and a pH of 8.0 (99.999% ionized) is small, decreases in tubular reabsorption cannot fully explain the rapid increase in urinary elimination seen at a pH above 7.0.

“Diffusion theory” offers a reasonable alternative explanation. Fick’s law of diffusion states that the rate of flow of a diffusing substance is proportional to its concentration gradient. A large concentration gradient between the nonionized salicylate in the peritubular fluid (and blood) and the tubular luminal fluid is found in alkaline urine. Because at a higher urinary pH, a greater proportion of secreted nonionized molecules quickly becomes ionized upon entering the alkaline environment, more salicylate (ie, nonionized salicylate) must pass from the peritubular fluid into the urine in an attempt to reach equilibrium with the nonionized fraction. In fact, as long as nonionized molecules are rapidly converted to ionized molecules in the urine, equilibrium in the alkaline milieu will never be achieved. The concentration gradient of peritubular nonionized salicylates to urinary nonionized salicylates continues to increase with increasing urinary pH. Hence, increased tubular diffusion, not decreased reabsorption, probably accounts for most of the increase in salicylate elimination observed in the alkaline urine.⁶⁵

Sodium bicarbonate is indicated in the treatment of salicylate poisoning for most patients with evidence of significant systemic toxicity. Although some authors have suggested alkali therapy for asymptomatic patients with concentrations above 30 mg/dL,¹¹⁸ limited data support this approach. For patients with chronic poisoning, salicylate concentrations are not as helpful and may be misleading; clinical criteria remain the best indicators for therapy. Patients with contraindications to sodium bicarbonate use, such as severe acute kidney injury (AKI) or chronic kidney disease (CKD) and acute respiratory distress syndrome (ARDS), should be considered candidates for intubation and subsequent hyperventilation, but extracorporeal removal is often required because of the difficulty and dangers of intubation.

Dosing recommendations depend on the acid–base considerations. For patients with hypobicarbonatemia, IV administration of 1 to 2 mEq of sodium bicarbonate per kilogram of body weight is recommended.¹¹² Alkalization can be maintained with a continuous sodium bicarbonate infusion of 150 mEq in 1 L of D₅W at 150 to 200 mL/h (or about twice the maintenance requirements in a child). Continued titration with sodium bicarbonate over 4 to 8 hours is recommended until the urinary pH reaches 7.5 to 8.0.^{109,112} The addition of the dextrose is important because salicylate toxicity may cause hypoglycemia.¹¹² Achieving a urinary pH of 8.0 is difficult but is the goal. Fastidious attention to the patient’s changing acid–base status is required. Systemic pH should not rise above 7.55 to prevent complications of alkalemia. Hypokalemia can make urinary alkalization particularly problematic.^{60,99} In hypokalemic patients, the kidneys preferentially reabsorb potassium in exchange for hydrogen ions. Urinary alkalization will be unsuccessful as long as hydrogen ions are excreted into the urine. Thus, appropriate potassium supplementation to achieve normokalemia may be required to alkalize the urine.¹²²

In the past, proper urinary alkalization was thought to require forced diuresis to maximize salicylate elimination.^{30,60} Suggestions included administering enough fluid (2 L/h) to produce a urine output of 500 mL/h. Because forced alkaline diuresis appears unnecessary and is potentially harmful as a result of its unnecessarily large fluid load, the goal is alkalization at a rate of approximately twice maintenance requirements to achieve a urine output of 3 to 5 mL/kg/h.

Phenobarbital

Although cardiopulmonary support is the most critical intervention in the treatment of patients with severe phenobarbital overdose, sodium bicarbonate may be a useful adjunct to general supportive care. The utility of sodium bicarbonate is particularly important considering the long plasma half-life (~100 hours) of phenobarbital. Phenobarbital is a weak acid (pK_a, 7.24) that undergoes significant renal elimination. As in the case of salicylates, alkalization of the blood and urine may reduce the severity and duration of toxicity. In a study of mice, the median anesthetic dose for mice receiving phenobarbital increased by 20% with the addition of sufficient sodium bicarbonate to increase the blood pH from 7.23 to 7.41, demonstrating decreased tissue concentrations associated with increased pH.¹¹⁵ The animal evidence has been extrapolated to humans to suggest that phenobarbital-poisoned patients in deep coma might develop a respiratory acidosis

secondary to hypoventilation, with the acidemia enhancing the phenobarbital transfer into the brain, thus worsening CNS and respiratory depression. Alternatively, increasing the pH with bicarbonate, ventilatory support, or both would enhance the phenobarbital efflux from brain, thus lessening toxicity. Given phenobarbital's relatively high pK_a , significant urinary phenobarbital accumulation is evident only when urinary pH is increased above 7.5.¹² As the pH approaches 8.0, a threefold increase in urinary elimination occurs. The urine-to-serum ratio of phenobarbital, although much higher in alkaline urine than in acidic urine, remains less than unity, thereby suggesting less of a role for tubular secretion than in salicylate poisoning.

Clinical studies examining the role of alkalization in phenobarbital poisoning have been inadequately designed. Many are poorly controlled and fail to examine the effects of alkalization, independent of coadministered diuretic therapy. In one uncontrolled study with phenobarbital overdoses, a 59% to 67% decrease in the duration of unconsciousness in patients occurred in patients administered alkali compared with nonrandomized control subjects.⁷¹ In other older studies, treatment with sodium lactate and urea reduced mortality and frequency of tracheotomy to 50% of control subjects, enhanced elimination, and shortened coma.^{59,74} In a later human volunteer study, urinary alkalization with sodium bicarbonate was associated with a decrease in phenobarbital elimination half-life from 148 to 47 hours.³⁵ However, this beneficial effect was less than the effect achieved by multiple-dose activated charcoal (MDAC), which reduced the half-life to 19 hours. In a nonrandomized study of phenobarbital-poisoned patients comparing urinary alkalization alone, MDAC alone, and both methods together, both the phenobarbital half-life decreased most rapidly and the clinical course improved most rapidly in the group of patients who received MDAC alone.⁷⁰ Interesting, the combination approach proved inferior to MDAC alone but was better than alkalization alone. The authors speculated that when both treatments were used together, the increased ionization of phenobarbital resulting from sodium bicarbonate infusion might have decreased the efficacy of MDAC. These studies suggest that MDAC is more efficacious than urinary alkalization in the treatment of phenobarbital-poisoned patients, although both approaches are beneficial and indicated.

Sodium bicarbonate therapy does not appear warranted in the treatment of patients with ingestions of other barbiturates, such as pentobarbital and secobarbital, which either have a pK_a above 8.0 or are predominantly eliminated hepatically.

Methotrexate

Urinary alkalization with sodium bicarbonate is routinely used during high-dose methotrexate cancer chemotherapy therapy.¹⁰⁸ Methotrexate is predominantly eliminated unchanged in the urine. Unfortunately, methotrexate, as well as its metabolites DAMPA (4-amino-4-deoxy-10-methylpteroic acid) and 7-hydroxymethotrexate, are poorly water soluble in acidic urine. Under these conditions, tubular precipitation of the methotrexate may occur, leading to AKI and decreased elimination, increasing the likelihood of methotrexate toxicity. Administration of sodium bicarbonate (as well as intensive hydration) during high-dose methotrexate infusions increases methotrexate solubility and the elimination of methotrexate and its metabolites.^{27,96}

Chlorophenoxy Herbicides

Alkalization is indicated in the treatment of patients with poisonings from weed killers that contain chlorophenoxy compounds, such as 2,4-dichlorophenoxyacetic acid (2,4-D) or 2-(4-chloro-2-methylphenoxy) propionic acid (MCP).⁸⁹ Poisoning results in muscle weakness, peripheral neuropathy, coma, hyperthermia, and acidemia. These compounds are weak acids (pK_a 2.6 and 3.8 for 2,4-D and MCP, respectively) that are excreted largely unchanged in the urine. In an uncontrolled case series of 41 patients poisoned with a variety of chlorophenoxy herbicides, 19 of whom received sodium bicarbonate, alkaline diuresis significantly reduced the half-life of each by enhancing renal elimination.³³ In one patient, resolution of hyperthermia and metabolic acidosis and improvement in mental status were associated with a transient elevation of serum concentration, perhaps reflecting chlorophenoxy compound redistribution from the tissues into the more alkalemic blood. The limited data suggest that the increased ionized fractions of the weak-acid chlorophenoxy compounds produced by alkalization is trapped in both the blood and the urine as demonstrated both with salicylates and phenobarbital; thus, its use ameliorates toxicity and shortens the duration of effect.

ROLE IN CORRECTING METABOLIC ACIDEMIA

Toxic Alcohols

Sodium bicarbonate has two important roles in treating patients with toxic alcohol ingestions. As an immediate temporizing measure, administration of sodium bicarbonate may reverse the life-threatening acidemia associated with methanol and ethylene glycol ingestions. In rats poisoned with ethylene glycol, the administration of sodium bicarbonate alone resulted in a fourfold increase in the median lethal dose.¹⁵ Clinically, titrating the endogenous acid with bicarbonate greatly assists in reversing the consequences of severe acidemia, such as hemodynamic instability and multiorgan dysfunction.

The second role of bicarbonate in the treatment of toxic alcohol poisoning involves its ability to favorably alter the distribution and elimination of certain toxic metabolites.⁹³ In cases of methanol poisoning, the proportion of ionized formic acid can be increased by administering bicarbonate, thereby trapping formate in the blood compartment.^{51,66} Consequently, decreased visual toxicity results from removal of the toxic metabolite from the eyes. In cases of formic acid (pK_a of 3.7) ingestion, sodium bicarbonate decreases tissue penetration of the formic acid and enhances urinary elimination.⁷³

Early treatment of acidemia with sodium bicarbonate is strongly recommended in cases of methanol and ethylene glycol poisoning.⁴³ Sodium bicarbonate should be administered to toxic alcohol-poisoned patients with an arterial pH below 7.30.⁵⁸ More than 400 to 600 mEq of sodium bicarbonate may be required in the first few hours.⁵⁰ In cases of ethylene glycol toxicity, sodium bicarbonate administration may worsen hypocalcemia, so the serum calcium concentration should be monitored. Combating the acidemia, however, is not the mainstay of therapy, and concurrent administration of IV fomepizole or ethanol and consideration for hemodialysis are almost always indicated.

Metformin

Metformin toxicity, either from overdose or therapeutic use in the setting of AKI or CKD, may cause severe, life-threatening metabolic acidemia with an elevated lactate concentration. The use of high-dose sodium bicarbonate to correct the metabolic acidemia, as well as extracorporeal removal of the metformin, is recommended in these cases.⁴²

ROLE IN NEUTRALIZATION

Chlorine Gas

Nebulized sodium bicarbonate serves as a useful adjunct in the treatment of patients with pulmonary injuries resulting from chlorine gas inhalation.^{4,25} Inhaled sodium bicarbonate neutralizes the hydrochloric acid that is formed when the chlorine gas reacts with the water in the respiratory tree. Although oral sodium bicarbonate is not recommended for neutralizing acid ingestions because of the problems associated with the exothermic reaction and production of carbon dioxide in the relatively closed gastrointestinal tract, the rapid exchange in the lungs of air with the environment facilitates heat dissipation. In a sheep model of chlorine inhalation, animals treated with 4% nebulized sodium bicarbonate solution demonstrated a higher PO_2 and lower PCO_2 than did the normal, saline-treated animals.²⁶ There was no difference, however, in 24-hour mortality or pulmonary histopathology. In a retrospective review, 86 patients with chlorine gas inhalation were treated with nebulized sodium bicarbonate.¹⁶ Sixty-nine patients were sent home from the emergency department, 53 of whom had clearly improved. In a more recent study, 44 patients who were diagnosed with reactive airway dysfunction syndrome after an acute exposure to chlorine gas were randomized to receive either nebulized sodium bicarbonate (4 mL of 4.2% sodium bicarbonate solution) or nebulized placebo.⁴ Both groups also received IV corticosteroids and inhaled β_2 -adrenergic agonists. Compared with the placebo group, the nebulized sodium bicarbonate group had significantly higher forced expiratory volume in 1 second (FEV_1) values at 120 and 240 minutes and scored significantly higher on a posttreatment quality of life questionnaire. Nebulized sodium bicarbonate failed to demonstrate a benefit in the treatment of chloramine gas exposure.⁸²

ROLE IN RENAL PROTECTION

Contrast Media

Although multiple meta-analyses suggest that hydration with sodium bicarbonate prevents contrast-induced nephropathy (CIN),^{49,52,76} other studies suggest no benefit.³⁹ A randomized trial of 119 patients compared an infusion of 154 mEq/L of either sodium bicarbonate or sodium chloride before (3 mL/kg for 1 hour) and after (1 mL/kg/h for 6 hours) iopamidol administration. CIN, defined as a 25% or greater increase in serum creatinine concentration within 2 days of contrast, occurred in eight patients in the sodium chloride group and one patient in the sodium bicarbonate group.⁶⁸ In another study comparing sodium bicarbonate with sodium chloride before emergency coronary angiography or intervention, the incidence of CIN was also significantly lower in the sodium bicarbonate group than in the sodium chloride group (7% vs. 35%).⁶⁷ However, in another recent study, an equal number of patients from the sodium bicarbonate and sodium chloride groups developed CIN.³⁹ It is suggested that increasing renal medullary pH with sodium bicarbonate infusion might protect the kidneys from oxidant injury by slowing free radical production. Although the addition of N-acetylcysteine to a sodium chloride hydration regimen to prevent CIN does not appear to offer any benefit compared with the use of only sodium chloride hydration,⁸⁰ the use of N-acetylcysteine and sodium bicarbonate together provides benefit compared with N-acetylcysteine and sodium chloride hydration.^{19,61} Whether N-acetylcysteine plus sodium bicarbonate is superior to sodium bicarbonate alone remains unproven.

Other Indications

Adverse effects and safety concerns may be associated with the dissociation of the dimercaprol (British anti-Lewisite {BAL}) metal binding that occurs in acid urine. Because dissociation of the BAL–metal chelate occurs in acidic urine, the urine of patients receiving BAL should be alkalinized with hypertonic sodium bicarbonate to a pH of 7.5 to 8.0 to prevent renal liberation of the metal.

Sodium bicarbonate may provide a renal protection benefit after exposure to depleted uranium. Animal studies suggest that sodium bicarbonate in conjunction with a chelator such as deferiprone may accelerate uranium excretion and reduce uranium nephrotoxicity.³⁶

ADVERSE EFFECTS AND SAFETY ISSUES

The use of sodium bicarbonate has associated risks. Concerns regarding excessive alkalemia, hypernatremia, fluid overload, hypokalemia, and hypocalcemia have all been raised.^{34,60,84,91,101} The package insert urges caution in patients with congestive heart failure, severe renal insufficiency, and preexisting edema with sodium retention.² Regarding its use to treat salicylism, early on, patients with pure respiratory alkalosis often have alkaluria and alkalemia and do not require urinary alkalization. Young children who rapidly develop metabolic acidosis often require alkalization but should be at less risk for complications of this therapy.⁷⁸ However, because hypertonic sodium bicarbonate has been reported to cause hypernatremia, decreased cerebrospinal fluid pressure, and possible intracranial hemorrhage in children younger than 2 years, the 4.2% solution may be preferred in these patients.² Extravasation has been reported to cause local tissue damage.² Dobutamine and norepinephrine are incompatible with sodium bicarbonate solutions, and calcium solutions may cause precipitation.

PREGNANCY AND LACTATION

According to the Food and Drug Administration (FDA), sodium bicarbonate is a Category C drug. The World Health Organization rates sodium bicarbonate as compatible with breastfeeding.

DOSING AND ADMINISTRATION

For the treatment of QRS prolongation in the setting of myocardial sodium channel poisoning, 1 to 2 mEq/kg of sodium bicarbonate should be initially administered IV as a bolus over a period of 1 to 2 minutes.⁸⁴ Greater amounts may be required to treat patients with unstable ventricular dysrhythmias.⁸⁸ Similar boluses can be repeated as needed to achieve a blood pH of 7.50 to 7.55.^{85,106} Because sodium bicarbonate has a brief duration of effect, a continuous infusion usually is required after the initial IV boluses. The treatment endpoint is the narrowing of the QRS interval. Excessive alkalemia (pH >7.55) and hypernatremia should be avoided. To prepare a sodium bicarbonate infusion three 50 mL ampules should be placed in 1 L of 5% dextrose in water (D₅W) and run at twice maintenance with frequent checks of QRS, potassium, and pH depending on the fluid requirements and blood pressure of the patient. Frequent evaluation of the fluid status should be performed to avoid precipitating pulmonary edema. An optimal duration of therapy has not been established.

For the treatment of salicylate poisoning, sodium bicarbonate can be administered by bolus or infusion using the dosing strategies described earlier until the urinary pH approaches 8. Careful and frequent monitoring of the urinary pH and serum potassium is critical to ensure optimal treatment. In salicylate-poisoned patients with altered mental status, aggressive administration of sodium bicarbonate may be required to ensure that the serum pH is greater than at least 7.40 to 7.45.

FORMULATIONS

The most commonly used sodium bicarbonate preparations are an 8.4% solution (1 M) containing 1 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 2000 mOsm/L) and a 7.5% solution containing 0.892 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 1786 mOsm/L). Fifty-milliliter ampules of the 8.4% and 7.5% solutions therefore contain 50 and 44.6 mEq of sodium bicarbonate, respectively. The common infant formulation is a 4.2% solution packaged as a 10 mL injectable ampule. This yields 5 mEq per container (0.5 mEq each of sodium and bicarbonate ions per mL). According to the package insert, the FDA approved indications for sodium bicarbonate include the “treatment of certain drug intoxications, including barbiturates (where dissociation of the barbiturate-protein complex is desired), in poisoning by salicylates or methyl alcohol, and in hemolytic reactions requiring alkalization of the urine to diminish nephrotoxicity of blood pigments. Urinary alkalization is also used in methotrexate therapy to prevent nephrotoxicity.”

SUMMARY

- Sodium bicarbonate remains an important antidote in the treatment of a wide variety of xenobiotic exposures.
- Sodium bicarbonate is effective in patients poisoned by myocardial sodium channel blockers by providing sodium through its effects on drug ionization and subsequent diffusion from the sodium channel binding site.
- Sodium bicarbonate is effective for salicylates, phenobarbital, methotrexate, and other weak acids because of its ability to “ion trap” in blood or urine compartments and mitigate target organ accumulation.
- Nebulized sodium bicarbonate may be effective in neutralizing inhaled acids such as chlorine gas.

B. FOOD, DIET, AND NUTRITION

CASE STUDY 2

History Parents called 911 because they found their 5 year-old girl at home unresponsive. Shortly before emergency medical services (EMS) arrived, the girl had a witnessed self limited seizure that the parents described as the sudden onset of unresponsiveness with repetitive shaking and urinary incontinence. When EMS arrived, she was no longer shaking but could not be aroused. The paramedics recorded a respiratory rate of 30 breaths/min with a pulse of 150 beats/min and a point-of-care glucose of 122 mg/dL. They administered oxygen via nasal cannula and brought her to the emergency department.

On arrival at the hospital, the parents reported that the child had no significant past medical history, had a pediatrician, was current with all vaccinations, and was not taking any prescription medications. Although she had a mild cough and nasal congestion, she was able to attend kindergarten the previous day. As further history was being obtained, the child began to shake repetitively once again.

Immediate Assessment and Management The child was given an intramuscular injection of lorazepam (2 mg; 0.1 mg/kg for an estimated weight of 20 kg) while an intravenous (IV) line was being inserted. Within a few moments the shaking stopped. Blood samples were sent for a complete blood count and electrolytes and an electrocardiogram (ECG) was ordered. The child was attached to continuous cardiac monitoring and repeat vital signs were: blood pressure, 108/80 mm Hg; pulse, 155 beats/min; respiratory rate, 32 breaths/min; rectal temperature, 99.4°F (37.4°C); oxygen saturation, 100% on a 100% nonrebreather face mask; and glucose, 143 mg/dL. Physical examination revealed a normal head without signs of trauma, pupils that were 4 to 5 mm and reactive, a clear chest, normal heart sounds, a soft abdomen with normal bowel sounds, and skin that was without rashes or other abnormalities. The child was still not verbal but appeared to localize pain and moved all extremities, and she had normal muscle tone. Unfortunately, the patient began to seize again. IV lorazepam (2 mg) was given with nearly an immediate response. Repeat vital signs and physical examination was essentially unchanged.

What Is the Differential Diagnosis? In addition to idiopathic epilepsy, trauma, infections, and structural brain lesions, seizures can result from exposure to countless xenobiotics and even withdrawal. In most instances, seizures are usually single and either self-limited or respond easily to an appropriate dose of a benzodiazepine. This child had three seizures in a brief period of time without regaining consciousness, which meets criteria for status epilepticus. Although seizures are common, status epilepticus is rare, thereby narrowing the differential diagnosis to xenobiotics found in [Table CS2–1](#).

TABLE CS2–1. Xenobiotics Commonly Associated with Status Epilepticus

Bupropion	Insulin secretagogues
Camphor	Isoniazid
Carbon Monoxide	Theophylline
Hyponatremia	

Is There a Clinical Difference between Drug-Induced Seizures and Idiopathic Epilepsy? Several features distinguish toxic-metabolic seizures from idiopathic epilepsy. First and foremost is that with few exceptions, toxic-metabolic seizures often fail to respond to phenytoin. Although phenytoin is an excellent second line anticonvulsant after benzodiazepines, it either has no efficacy or is actually detrimental in diverse toxicological etiologies from alcohol withdrawal or seizures induced by dysrhythmias, theophylline, cyclic antidepressants, anticonvulsants, and or cocaine. Conceptually, phenytoin fails because its ability to prevent secondary generalization of a focal seizure in idiopathic epilepsy is lost in toxic-metabolic etiologies where many areas of the brain are likely coming to threshold simultaneously. Thus, when a toxic-metabolic cause is suspected, typically a barbiturate or propofol is added when benzodiazepines fail. In some cases, such as isoniazid, an antidote may be necessary ([Antidotes in Depth: A14](#)), and in others, such as theophylline, hemodialysis or hemoperfusion may be indicated ([Chap. 10](#)). Finally, it is important to recognize that the cessation of motor activity with toxic-metabolic seizures may be insufficient to prevent serious complications. For example, although it is likely that patients with hypoglycemia, hyponatremia, or carbon monoxide poisoning can have their seizures terminated with benzodiazepines, the failure to correct these underlying issues will likely prevent complete neurological recovery. The reader is referred to [Antidotes in Depth: A23](#) for information regarding the choice, dose, and route of commonly used benzodiazepines.

What Rapid Clinical and Laboratory Analyses Can Help Exclude Life Threatening Causes of This Patient's Presentation? Many rapidly reversible causes of seizures can be assessed by the history and physical examination.

Signs and symptoms of trauma, infection, and structural brain injury are often immediately evident. Bedside techniques can assess hypoxia, hypercarbia, and hypoglycemia, and a venous blood gas can confirm or exclude hyponatremia and dyshemoglobinemias ([Chaps. 19, 29, 53, and 125](#)). An ECG provides rapid information confirmation of sodium channel blockade, a frequent cause of seizures ([Chaps. 16 and 71](#)) and potassium channel blockade that might produce torsade de pointes ([Chaps. 16, 70, and 92](#)), which causes syncope that can be confused with seizures in unmonitored patients. Vomiting would be commonly expected following overdose, especially with isoniazid ([Chap. 58](#)) and theophylline ([Chap. 66](#)). In some patients, computed tomography (CT) of the head, lumbar puncture, and empiric antibiotics and antivirals may be indicated.

Further Diagnosis and Treatment Because of the child's continued depressed mental status, a clinical decision was made to protect her airway. During preparation for intubation, a unique odor was noted in the oropharynx. When the parents were questioned, they confirmed that they had bought camphor ([Chap. 105](#)) for use in a vaporizer in an attempt to help relieve the symptoms of an upper respiratory tract infection. The child had likely eaten some for unclear reasons. Intubation was not performed when this history was obtained, because the girl's mental status appeared to be improving. A head CT scan was obtained without contrast and was interpreted as normal. Over the next day, the girl awakened and was neurologically normal. She was discharged after her parents were counseled about chemical and medication safety.

40 ATHLETIC PERFORMANCE ENHANCERS

Susi U. Vassallo

HISTORY AND EPIDEMIOLOGY

Interest in extraordinary athletic achievement fuels the modern day science of performance enhancement in sports. The desire to improve athletic performance in a scientific manner is a relatively recent development. At one time, the focus on maximizing human physical and mental potential centered on the importance of manual work and military service. The role of sport was inconsequential, except for its potential in improving military preparedness.⁹² Today, “sports doping” refers to the use of a prohibited xenobiotic to enhance athletic performance. The word doping comes from the Dutch word *doop*, a viscous opium juice used by the ancient Greeks.²⁸

Controversy surrounding the systematic use of performance enhancing xenobiotics by the participating athletes has marred many sporting events. Since the International Olympic Committee (IOC) began testing during the 1968 Olympic games, prominent athletes have been sanctioned and stripped of their Olympic medals because they tested positive for banned xenobiotics. However, from a public health perspective, the use of performance-enhancing drugs among athletes of all ages and abilities is a far more serious concern than the highly publicized cases involving world class athletes. The majority of studies on the epidemiology of performance enhancing xenobiotics have investigated androgenic anabolic steroid use. Androgenic means masculinizing, and anabolic means tissue building. An anabolic process stimulates protein synthesis, promotes nitrogen deposition in lean body mass, and decreases protein breakdown. Studies of high school students document that 6.6% of male seniors have used anabolic steroids, and 35% of these individuals were not involved in organized athletics.³¹ Others find rates of androgenic steroid use in adolescent athletes range from 3% to 19%.^{101,114,170,226,231,232} Of the 243,193 samples analyzed by accredited laboratories for the presence of banned performance enhancing xenobiotics in Olympic and non-Olympic sports, 2% had positive findings. The majority of these findings are specific for anabolics and stimulants.

PRINCIPLES

Performance enhancers can be classified in several ways. Some categorize performance enhancers according to the expected effects. For example, some xenobiotics increase muscle mass, whereas others decrease recovery time, increase energy, or mask the presence of other xenobiotics. However, one xenobiotic may have several expected effects. For example, diuretics may be used to mask the presence of other xenobiotics by producing dilute urine, or they may be used to reduce weight. Clenbuterol is an anabolic xenobiotic, but it also is a stimulant because of its β_2 -adrenergic agonist effects. Depending on the xenobiotic, it is used either during training to improve future performance or during competition to improve immediate results.²⁸

According to the 2013 World Anti-Doping Agency (WADA) World Anti-Doping Code, a xenobiotic or method constitutes doping and can be added to the Prohibited List if it is a masking xenobiotic or if it meets two of the following three criteria: it enhances performance, its use presents a risk to the athlete’s health, and it is contrary to the spirit of sport²³⁰ (Table 40–1). Some of the prohibited substances and methods on the WADA 2013 Prohibited List are used to treat legitimate medical conditions of athletes.²³⁰ Athletes with documented medical conditions requiring the use of a prohibited substance or method may request a therapeutic use exemption (TUE). For example, the use of a β -adrenergic agonist other than albuterol, salbutamol, or formoterol in an athlete with documented asthma requires a TUE.

TABLE 40–1. Abbreviated Summary of World Anti-Doping Agency 2013 Prohibited List²³⁰

Substances (S) and Methods (M) Prohibited at All Times (In and Out of Competition)

S1. Anabolic Agents

- Anabolic Androgenic Steroids
- Other Anabolic Agents

Clenbuterol

Selective androgen receptor modulators

S2. Peptide Hormone, Growth Factors, and Related Agents

Erythropoiesis stimulation agents

Chorionic gonadotropin and luteinizing hormone

Corticotropins

Growth hormone

S3. β_2 -Adrenergic Agonists

Except inhaled salbutamol, formoterol, and salmeterol with urinary concentration limits

S4. Hormone Antagonists and Metabolic Modulators

Aromatase inhibitors

Selective estrogen receptor modulators

Antiestrogens

Myostatin modulators

Metabolic modulators

Insulins

Peroxisome proliferator activated receptor delta agonist and AMP activate protein kinase axis agonists

S5. Diuretics and Other Masking Agents

Prohibited Methods

M1. Manipulation of Blood and Blood Components

M2. Chemical and Physical Manipulation

Tampering with samples

Intravenous infusions

M3. Gene Doping

Substances (S) and Methods (M) Prohibited in Competition

In addition to the above, the following categories are prohibited only in competition:

S6. Stimulants

S7. Narcotics

S8. Cannabinoids

S9. Glucocorticosteroids

Substances Prohibited in Particular (P) Sports

P1. Alcohol

P2. β -Adrenergic Antagonists

Specified Substances^a

- Ephedrine
- Cannabinoids
- All inhaled β_2 -adrenergic agonists, except clenbuterol
- Probenecid
- All glucocorticosteroids
- All β -adrenergic antagonists
- Alcohol in competition only

^aIn certain circumstances, a doping violation involving specified substances may result in a reduced sanction, provided the athlete establishes that the use was not intended to enhance performance.

ANABOLIC XENOBIOTICS

Anabolic Androgenic Steroids

Anabolic-androgenic steroids (AASs) increase muscle mass and lean body weight, and cause nitrogen retention.¹⁴⁵ The androgenic effects of steroids are responsible for male appearance and secondary sexual characteristics such as increased growth of body hair and deepening of the voice. Testosterone is the prototypical androgen, and most AASs are synthetic testosterone derivatives. The WADA categorizes AASs into two groups: exogenous, referring to substances that are not ordinarily capable of being produced by the body naturally, and endogenous, referring to those capable of being produced by the body naturally. As such, there is sometimes discordance in categorization schemes with other governing entities. In this document, the term anabolic steroid means any xenobiotic, chemically and pharmacologically related to testosterone, other than estrogens, progestins, corticosteroids, and DHEA.

In the 1970s and 1980s, federal regulation of anabolic steroids was under the direction of the Food and Drug Administration (FDA). Because of increasing media reports on the use of AASs in sports, particularly by high school students and amateur athletes, Congress enacted the Anabolic Steroid Control Act of 1990, which amended the Controlled Substances Act and placed anabolic steroids in schedule III. Schedule III implies that a xenobiotic has a currently accepted medical use in the United States and has less potential for abuse than the drugs categorized as schedule I or II. The Anabolic Steroid Control Act of 2004 adds certain steroid precursors, such as androstenedione and dihydrotestosterone, to the list of controlled substances that are considered illegal without a prescription. However, DHEA is exempted. Possession of androstenedione or other metabolic precursors called prohormone drugs is considered a federal crime. Nevertheless, AASs are still available illicitly over the Internet from international marketers, veterinary pharmaceutical companies, and some legitimate US manufacturers (Table 40–2).

TABLE 40–2. Synthetic Testosterone Derivatives/Anabolic Androgenic Steroids: Generic Nomenclature

<i>17α-Alkyl Derivatives (Oral)</i>	<i>17β-Ester Derivatives (Parenteral)</i>	<i>Testosterone Preparations (Topical)</i>
Ethylestrenol	Boldenone	Buccal gel, sublingual
Fluoxymesterone	Nandrolone decanoate	Dermal gel, ointment
Methandrostenolone	Nandrolone	Transdermal reservoir
Methyltestosterone	phenpropionate	patch
Oxandrolone	Testosterone esters	
Oxymetholone	Testosterone cypionate	
Stanozolol	Testosterone enanthate	
	Testosterone ester	
	combination	
	Testosterone propionate	
	Trenbolone	

Antiestrogens and Antiandrogens

In male athletes using androgens, avoiding the unwanted side effects of feminization, such as gynecomastia, or in female athletes, avoiding masculinization and features such as facial hair and deepening voice, requires manipulation of the metabolic pathways of androgen metabolism. Creating a xenobiotic that completely dissociates the desired from the unwanted effects has not been possible. However, xenobiotics with properties capable of manipulating metabolic pathways associated with undesirable side effects are divided into four main groups, all on the Prohibited List.

1. Aromatase inhibitors such as anastrozole and aminoglutethimide prevent the conversion of androstenedione and testosterone into estrogen.
2. The antiestrogen clomiphene blocks estrogen receptors in the hypothalamus, opposing the negative feedback of estrogen, causing an increase in gonadotropin-releasing hormone, thereby increasing testosterone release.
3. Selective estrogen receptor modulators (SERMs) such as tamoxifen and raloxifene bind to estrogen receptors and exhibit agonist or antagonist effects at the estrogen receptors. By indirectly increasing gonadotropin release, SERMs restore endogenous testosterone production upon discontinuation of AASs.¹⁷⁸
4. Selective androgen receptor modulators (SARMs) are nonsteroidal tissue selective anabolic xenobiotics. SARMs are neither aromatized and are not substrates for 5 α -reductase, nor do they undergo the same metabolic pathways as testosterone. Therefore, they have fewer unwanted androgenic side effects.^{73,209}

Administration

Approximately 50% of AASs are taken orally. The remainder are administered by intramuscular injection, with one-fourth of intramuscular users sharing needles.^{53,152} One third of the needles and syringes exchanged in a needle-exchange program in Wales were used for AAS injections.¹⁵⁹ Unlike therapeutically indicated regimens, which consist of fixed doses at regular intervals, athletes typically use AASs in cycles of 6 to 8 weeks.¹² For example, the athlete may use steroids for 2 months and then abstain for 2 months. Cycling is based on the athlete's individual preferences and not on any validated protocol. Stacking implies combining the use of several AASs at one time, often with both oral and intramuscular administration. To prevent plateauing, or developing tolerance, to any one xenobiotic, some athletes use an average of five different AASs simultaneously. The doses used are frequently hundreds of times in excess of scientifically based therapeutic recommendations.^{3,227} Pyramiding implies starting the AASs at a low dose, increasing the dose many times, and then tapering once again. Fat soluble steroids may require several months to be totally eliminated, whereas water soluble steroids may require only days to weeks to be cleared by the kidney. Water soluble testosterone esters are used for "bridging therapy." Bridging refers to the practice of halting the administration of long lasting alkylated testosterone formulations so that urine analyses at a specific time offer no evidence of use, whereas injections of shorter acting testosterone esters are used to replace the orally administered alkylated formulations. This strategy, which was used extensively in the German Democratic Republic, is documented in a review of the subject based on extensive research of previously classified records.⁶⁵ Clearance profiles for testosterone congeners were determined for each athlete. In general, the daily injection of testosterone esters was used when termination of the more readily detectable synthetic alkylated testosterone derivatives was necessary to avoid a positive doping test. These daily injections of testosterone propionate were halted 4 to 5 days before competition. Corrupt officials involved in doping were sure that the values would decrease to acceptable concentrations in time for the event, based on the science of athletes' clearance of testosterone esters.⁶⁵

Clinical Manifestations of Anabolic-Androgenic Steroid Use

Cancer. An association between AAS use and the development of cancer is observed in experimental animals.¹⁸⁰ Testicular and prostatic carcinomas are reported in more frequent users of anabolic-androgenic steroids.^{61,71,179} Hepatocellular carcinoma,^{100,153} cholangiocarcinoma,^{12,80} Wilms tumor, and renal cell carcinoma are also reported in young AAS users.^{30,169} The relationship between the dose of AASs and cancer is unknown.

Cardiovascular. Cardiac complications include acute myocardial infarction, venous thromboembolism, and sudden cardiac arrest.^{7,64,87,96,127,129,131,141} Autopsy examination of the heart may reveal biventricular hypertrophy, extensive myocardial fibrosis, and contraction-band necrosis. Myofibrillar disorganization as well as hypertrophy of the interventricular septum and left ventricle are present.¹²⁹ Intense training and use of AASs impair diastolic function by increasing left ventricular wall thickness. Animal models and in vitro myocardial cell studies show similar pathologic changes.^{45,113,142,208,216,217} Doppler echocardiography shows that several years after strength athletes discontinue using AASs, excessive concentric left ventricular hypertrophy remains. Growth hormone may potentiate the effects of AASs and further increase concentric remodeling of the left ventricle.¹⁰⁵ In addition to direct myocardial injury, vasospasm or thrombosis may occur.¹⁴² Alkylated androgens lower the concentration of high-density lipoprotein (HDL) cholesterol and may increase platelet aggregation.^{3,64} Thromboembolic complications include pulmonary embolus,^{50,72} stroke,^{109,110,196} carotid arterial occlusion,¹²⁰ cerebral sinus thrombosis,¹¹⁷ poststeroid balance disorder,²⁶ and popliteal artery

entrapment.¹²⁵

Dermatologic/Gingiva. Cutaneous side effects are common and include keloid formation, sebaceous cysts, comedones, seborrheic furunculosis, folliculitis, and striae.¹⁹² Acne is associated with steroid use and sometimes is referred to as “gymnasium acne.”^{39,162} A common triad of acne, striae, and gynecomastia occurs. The production of sebum is an androgen-dependent process, and dihydrotestosterone is active in sebaceous glands.¹² Gingival hyperplasia is reported.¹⁵⁴

Endocrine. Conversion of AASs to estradiol in peripheral tissues results in feminization of male athletes. Gynecomastia may be irreversible. AAS use causes negative feedback inhibition of gonadotropin-releasing hormone, luteinizing hormone, and follicle-stimulating hormone from the hypothalamus. This process results in testicular atrophy and decreased spermatogenesis, which may be reversible. In women, menstrual irregularities and breast atrophy may occur.²⁰⁶

Hepatic. Hepatic subcapsular hematoma with hemorrhage is reported.¹⁹¹ Peliosis hepatis, a condition of blood-filled sinuses in the liver that may result in fatal hepatic rupture, occurs most commonly with alkylated androgens and may not improve when androgen use is stopped.^{13,91,198,225} This condition is not associated with the dose or duration of treatment.^{12,99,201} Cyproterone acetate is a chlorinated progesterone derivative that inhibits 5 α -reductase and reportedly causes hepatotoxicity.^{12,70,75}

Infectious. Local complications from injection include infected joints,⁶⁰ cutaneous abscess,^{137,173} and *Candida albicans* endophthalmitis.²²⁶ Injection of AASs using contaminated needles has led to transmission of infectious diseases such as human immunodeficiency virus and hepatitis B and C.^{152,155,172,175,193,197} Severe varicella is reported in long-term AAS users.¹⁰¹

Musculoskeletal. Supraphysiologic doses of testosterone, when combined with strength training, increase muscle strength and size.²² The most common musculoskeletal complications of steroid use are tendon and ligament rupture.^{67,89,121,126}

Neuropsychiatric. Distractibility, depression or mania, delirium, irritability, insomnia, hostility, anxiety, mood lability, and aggressiveness (“roid rage”) may occur.^{17,68,166,167,207} These neuropsychiatric effects do not appear to correlate with serum AAS concentrations.^{196,207} Withdrawal symptoms from AAS include decreased libido, fatigue, and myalgias.^{108,232}

Specific Anabolic Xenobiotics

Dehydroepiandrosterone. DHEA is a precursor to testosterone (Fig. 40–1). Because it is produced endogenously, DHEA most commonly is not categorized as an AAS. However, DHEA is weakly anabolic and weakly androgenic. Although banned by the FDA in 1996, this xenobiotic subsequently was marketed as a nutritional supplement and is available for purchase without a prescription.²⁰⁶ DHEA is converted to androstenedione and then to testosterone by the enzyme 17 β -hydroxysteroid dehydrogenase.^{94,128,132} Administration of androstenedione in dosages of 300 mg/d increases testosterone and estradiol concentrations in some men and women.¹²⁴ Women with adrenal insufficiency given DHEA replacement at a dose of 50 mg/d orally for 4 months demonstrated increased serum concentrations of DHEA, androstenedione, testosterone, and dihydrotestosterone. Serum total and HDL cholesterol concentrations simultaneously decreased. Some women experienced androgenic side effects, including greasy skin, acne, and hirsutism.¹⁰ Sense of well-being and sexuality increased in men and women after 4 months of treatment.^{10,146,147} The neuropsychiatric effects of DHEA have been demonstrated in animals. Increased hypothalamic serotonin, anxiolytic effects, antagonism at the γ -aminobutyric acid type A (GABA_A) receptor, and agonism at the N-methyl-D-aspartate receptor (NMDA) are demonstrated.^{10,133,143}

FIGURE 40–1. Metabolic pathway of dehydroepiandrosterone (DHEA).

Clenbuterol. Clenbuterol is a β_2 -adrenergic agonist that decreases fat deposition and prevents protein breakdown in animal models.^{6,38,90} Clenbuterol is also a potent nutrient partitioning agent, a term implying it can increase the amount of muscle and decrease the amount of fat produced per pound of feed given to cattle and other animals.^{68,177} Use of clenbuterol in cattle farming is illegal in many countries. Nevertheless, the consumption of veal liver contaminated with clenbuterol has resulted in sympathomimetic symptoms and positive urine tests in affected individuals.¹⁸³ Clenbuterol is composed of a racemic mixture of (+) and (–) stereoisomers, eliminated in urine in approximately equal amounts. As clenbuterol accumulates in animal meat, stereoisomer ratios change over time and (–) clenbuterol is depleted. By analyzing urinary ratios of clenbuterol stereoisomers, it is possible to differentiate administration of therapeutic clenbuterol preparations from inadvertent ingestion of clenbuterol in meat products.²¹¹ Clenbuterol increases the glycolytic capacity of muscle and causes hypertrophy, enhancing the growth of fast-twitch fibers^{134,234} (Chap. 66).

PEPTIDES AND GLYCOPROTEIN HORMONES

Creatine

Creatine is an amino acid formed by combining the amino acids methionine, arginine, and glycine. It is synthesized naturally by the liver, kidneys, and pancreas. Creatine is found in protein-containing foods such as meat and fish.¹⁵⁴ In its phosphorylated form, it is involved in the rapid resynthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) by acting as a substrate to donate phosphorus.²⁰⁵ Because ATP is the immediate source of energy for muscle contraction, creatine is used by athletes to increase energy during short, high-intensity exercise.²²⁰ More than 2.5 million kilograms of creatine are consumed annually in the United States.⁵⁶ Exceptional athletes have admitted to using creatine as part of their training nutritional regimen, leading to interest by athletes at all levels. Numerous studies demonstrate improved performance with creatine supplementation, particularly in sports requiring short, high-intensity

effort.^{25,31,84,116,140,220} Creatine is found in skeletal muscle and in the heart, brain, and kidney. Two-thirds of creatine is stored primarily as phosphorylated creatine and the remainder as free creatine.¹⁴ Consuming carbohydrates with creatine supplements increases total creatine and phosphorylated creatine stores in skeletal muscle.⁸³ This process explains why creatine is marketed in combination with carbohydrate. Human endogenous creatine production is 1 g/d, and normal diets containing meat and fish offer another 1 to 2 g/d as dietary intake. One to two grams of creatine is eliminated daily by irreversible conversion to creatinine.²²⁴

Creatine supplementation is most commonly accomplished with creatine monohydrate. A dose of 20 to 25 g/d can increase the skeletal muscle total creatine concentration by 20%.^{84,97} Creatine stores do not increase in some individuals despite creatine supplementation. Creatine uptake in skeletal muscle occurs via the creatine transporter proteins at the sarcolemma. Creatine transporter expression and activity, as well as exercise and training, influence the uptake of creatine and the effect of creatine loading on athletic performance.^{199,200,202}

One adverse effect of creatine supplementation is weight gain, which is thought to result primarily from water retention.^{84,140} However, evidence indicates that net protein increase is partially responsible for the weight gain associated with long-term creatine use.¹⁰⁴ Diarrhea was the most commonly reported side effect of creatine use in one study of 52 male college athletes. Other complaints were muscle cramping and dehydration, although many subjects had no complaints.¹⁰³

Creatine supplementation increases urinary creatine and creatinine excretion and may increase serum creatinine concentrations by 20%.^{84,104} Long- and short-term creatine supplementation does not appear to have an adverse effect on kidney function.^{164,165} One patient who had been taking creatine 5 g/d for 4 weeks developed interstitial nephritis that improved with cessation of creatine use. Whether ingestion of creatine caused the nephritis is unknown.¹¹⁵ A young man with focal segmental glomerular sclerosis developed an elevated creatinine concentration and decreased glomerular filtration rate when creatine supplementation was started. The values returned to baseline upon cessation of creatine supplementation.¹⁷¹ The possibility of developing decreased kidney function is a theoretical concern. Ingestion of large amounts of creatine may result in formation of the carcinogenic substance N-nitrososarcosine, which induces esophageal cancer in rats.^{8,9}

Human Growth Hormone

Human growth hormone (hGH) is an anabolic peptide hormone secreted by the anterior pituitary gland. It stimulates protein synthesis and increases growth and muscle mass in children. Recombinant hGH (rhGH) has been available since 1984. It is commonly used therapeutically for children with growth hormone deficiency in daily doses of 5 to 26 µg/kg body weight.²²¹

Growth hormone secretion is stimulated by growth hormone–releasing hormone and is inhibited by somatostatin. Growth hormone receptors are found in many tissues, including the liver. Binding of hGH to hepatic receptors causes secretion of insulinlike growth factor-1 (IGF-1), which has potent anabolic effects and is the mediator for many of the actions of hGH.

Release of hGH, which occurs mainly during sleep, occurs in a pulsatile manner. Exercise stimulates hGH release, and more intense exercise causes proportionately more hGH release.^{27,43,206} Amino acids such as ornithine, L-arginine, tryptophan, and L-lysine, increase hGH release through an unknown mechanism and often are ingested for this purpose.^{43,86}

By causing nitrogen retention and increased movement of amino acids into tissue, hGH stimulates protein synthesis and tissue growth. The effects on increasing muscle mass and size are demonstrated in growth hormone–deficient individuals. Some studies do not support an increase in strength secondary to the increase in muscle size in athletes,^{41,130} whereas others demonstrate lean body mass, strength, and power increases.⁸² Growth hormone improves muscle and cardiac function, increases red cell mass and oxygen-carrying capacity, stimulates lipolysis, normalizes serum lipid concentrations, and decreases subcutaneous fat. It also improves mood and sense of well-being.^{41,42,88,185,206,221}

Growth hormone is used by athletes for its anabolic potential. As a xenobiotic of abuse, it is particularly attractive because laboratory detection is difficult. In one survey, 12% of people in gyms used hGH for body building.⁵⁹ In another survey of adolescents, 5% of 10th-grade boys had used hGH.¹⁷⁶ It may be sold illicitly as recombinant hGH.

Administration of hGH may cause myalgias, arthralgias, carpal tunnel syndrome, and edema.⁹⁵ The effects of hGH on skeletal growth depend on the user's age. In preadolescents, excessive hGH may cause increased bony growth and gigantism. In adults, excessive hGH may cause acromegaly.^{217,219} Growth hormone may cause glucose intolerance and hyperglycemia. Skin changes, such as increased melanocytic nevi and altered skin texture, occur.¹⁶³ Lipid profiles may be adversely affected. HDL concentrations are decreased, a change associated with increased risk of coronary artery disease.²³⁵ Because hGH must be given parenterally, there is risk of transmission of infection.¹³⁰ The illicit sale of cadaveric human pituitary-derived growth hormone is associated with a risk of Creutzfeldt-Jakob disease.⁴⁹ Long-term users of hGH may be at increased risk for prostate cancer because of the complications associated with IGF-1⁷⁹ (see

below).

Testing for hGH is plagued by the difficulties inherent in testing for exogenous peptide doping in general—the identical amino acid sequences of both rhGH and hGH; the fluctuating, pulsatile secretion; short half-life; and variation in normal concentration depending on sleep as well as stress and exercise status. Unlike the ability to use the differing pattern of N-linked glycosylation in hEPO produced in the human kidney to distinguish it from rhEPO produced in the hamster, hGH has no N-linked glycosylation sites to facilitate differentiation.

There are currently two approaches to detection of hGH currently: the marker approach and the isoform approach.⁹³ The marker approach uses an immunoassay to measure hGH-dependent factors through which hGH exerts its effect, such as IGF-1 and insulinlike growth factor binding proteins, as well as other markers of bone growth and turnover, such as the N-terminal extension peptide of procollagen type III.^{23,168} The isoform approach refers to the measurement of the various forms of growth hormone. Whereas rhGH is primarily a 22-kDa monomeric form, pituitary hGH contains multiple isoforms. In athletes using rhGH, endogenous hGH with its multiple isoforms is suppressed through negative feedback on the pituitary. Therefore, the 22-kDa form characteristic of rhGH becomes predominant. The ratio of isoforms, as measured by immunoassay, changes.

Insulinlike Growth Factor-1

IGF-1 is a peptide chain structurally related to insulin. A recombinant form is available.¹⁷⁶ Parenteral administration of IGF-1 is approved for clinical treatment of dwarfism and insulin resistance. Children who develop antibodies to rhGH may respond to IGF-1.

The primary stimulus for release of IGF-1 is hGH, although insulin, DHEA, and nutrition play a role.^{146,182} The actions of IGF-1 can be classified as either anabolic or insulinlike.¹⁸² The effects of growth hormone are primarily mediated by IGF-1. IGF-1 is produced in the liver and many other cell types. IGF-1 binds principally to the type I IGF receptor, which has 40% homology with the insulin receptor and a similar tyrosine kinase subunit.²¹³ IGF-1 also binds to insulin receptors, but it has only 1% of insulin affinity for the insulin receptor. IGF-1 increases glucose utilization by causing the movement of glucose into cells, increasing amino acid uptake and stimulating protein synthesis.

Side effects are similar to those associated with use of growth hormone and include acromegaly. Other effects include headache, jaw pain, edema, and alterations in lipid profiles. A potentially serious side effect of IGF-1 is hypoglycemia. High endogenous plasma IGF-1 concentrations are associated with an increased risk for prostate cancer.³⁶

Few studies on the efficacy of IGF-1 in improving the conditioning of athletes are available. IGF-1 can be considered favorably by female athletes because it does not cause virilization.²⁰⁶

Insulin

Insulin is used by body builders for its anabolic properties. Of 20 self-identified AAS users in a single gym, 25% who had no medical reason to take insulin reported using it to increase muscle mass.¹⁷⁴ These individuals stated that they had injected insulin from 20 to 60 times over the 6 months prior to the study.¹⁷⁴ Their practice was to inject 10 units of regular insulin and then eat sugar-containing foods after injection. As expected, hypoglycemia is reported in body builders using insulin.^{56,98,171}

Insulin inhibits proteolysis and promotes growth by stimulating movement of glucose and amino acids into muscle and fat cells. It increases the synthesis of glycogen, fatty acids, and proteins⁴⁴ (Chap. 53).

Human Chorionic Gonadotropin (hCG)

In men, the glycoprotein hCG stimulates testicular steroidogenesis. In women, hCG is secreted by the placenta during pregnancy. It may be used by male athletes to prevent testicular atrophy during and after androgen administration.¹¹¹ Analysis of hCG in 740 urinary specimens of male athletes revealed abnormal concentrations in 21 individuals. This finding prompted the IOC ban on hCG use in 1987.^{30,43} Presently, distinguishing exogenous hCG administration from hCG production in early pregnancy is not possible, so the urine samples of women are not tested.¹¹¹

Very small amounts of hCG are normally present in men and nonpregnant women.¹²¹ Currently, measurement is made by immunoassay. The decision limit, the concentration at which the test is considered positive, is set at 5 IU/mL urine. Trophoblastic tumors and nontrophoblastic tumors can increase hCG concentrations, and this possibility must be considered in the evaluation of elevated urinary hCG concentration.⁴⁸ Administration of hCG causes an increase in the total testosterone and epitestosterone produced.

OXYGEN TRANSPORT

Erythropoietin (EPO)

Human erythropoietin (hEPO) is a hormone that, through a receptor-mediated mechanism, induces erythropoiesis by stimulating stem cells. EPO has been available since 1988 as recombinant human erythropoietin (rhEPO), and its use in international competition has been prohibited since 1990. While hEPO is produced primarily by the kidneys, rhEPO is produced in hamsters⁵²; this results in differing glycosylation patterns, an important piece in the laboratory detection of EPO in sports doping.

Because EPO increases exercise capacity and hemoglobin production, it is used by athletes, often with additional iron supplementation. The clinical effects of increased hemoglobin occur several days after administration.^{69,156} EPO increases maximal oxygen uptake by 6% to 7%, an effect that lasts approximately 2 weeks after rhEPO administration is completed.⁵⁵

Two EPO analogs exist. Darbepoetin, also known as new erythropoiesis-stimulating protein, differs from EPO by five amino acids. It has a much longer half-life and can be injected weekly.¹⁵⁷ Another protein, known as synthetic erythropoiesis protein, has a similar protein structure to EPO. The protein polymers created in this molecule have less immunogenicity, fewer biologic contaminants, and more predictable pharmacokinetics.¹⁵⁷

Human EPO is secreted primarily by the kidney, although some is produced by the liver. The mean apparent half-lives of rhEPO are 4.5 hours following intravenous administration and 25 hours after subcutaneous administration.¹⁸⁴

EPO enhances endothelial activation and platelet reactivity and increases systolic blood pressure during submaximal exercise.^{21,204} These effects, in addition to the increase in hemoglobin, increase the risk of thromboembolic events, hypertension, and hyperviscosity syndromes.^{21,139,156} Nineteen Belgian and Dutch cyclists died of uncertain causes between 1987 and 1990.⁵⁴ Increases in hematocrit subsequent to EPO use are believed to have contributed to these deaths. The 1998 Tour de France was marred by the discovery of widespread EPO use by members of several different cycling teams.

An EPO overdose occurred in a patient who self-administered 10,000 units/d for an unknown period of time as a result of a dosing error. The patient presented to the hospital with confusion, a plethoric appearance, blackened toes, decreased pulses, and a hematocrit of 72%. Emergent erythropheresis was performed and resulted in rapid reduction of hematocrit and improvement in the patient's condition.²³³ Another report of deliberate daily self-administration of an unknown dose of rhEPO resulted in a hematocrit of 70%. The patient was treated emergently with phlebotomy and intravenous hydration and improved.²⁹

Testing for Erythropoietin. EPO is directly measured by a monoclonal anti-EPO antibody test, which does not distinguish between endogenously produced and exogenously administered recombinant EPO. Therefore, indirect methods of EPO detection are used, such as measurement of hemoglobin or hematocrit.

Previously, some sports-governing bodies, such as the International Cycling Federation and the International Skiing Federation, selected a hematocrit of 50% in men and 47% in women as the action level above which an athlete may be disqualified for presumed EPO use. However, normal hematocrit values vary greatly among athletes. Several studies have shown that hematocrits above the action values of 50% in men and 47% in women are common in athletes. From 3% to 6% of athletes who did not use EPO had hematocrits greater than 50%.²²² Of those athletes living and training at altitudes between 2000 and 3000 meters above sea level, 20.5% had hematocrit values higher than 50%.²²² Other studies confirm the increased hematocrits of athletes training at altitudes of 1000 to 6000 meters.^{19,188,189,222}

Although many endurance athletes may have increased blood volume, the hematocrit may be lowered because of the increased plasma volume, which exceeds the RBC volume. This dilutional pseudoanemia is sometimes called sports anemia.¹⁹⁵ Additionally, hematocrit measurements are affected by hydration status, posture (upright versus supine), and nutrition, and they demonstrate an approximately 3% diurnal variation.¹⁸⁷ Because of natural variations among individuals, postural effects, and the ease of manipulation through saline infusion, indirect detection of EPO use by hematocrit measurement is fraught with potential for error.¹⁵⁶

Several methods have been studied to detect the use of rEPO by athletes. The ratio between serum soluble transferrin receptors (sTfr) and ferritin was used as an indirect method for detection of EPO use. The sTfr is released from RBC progenitors. EPO stimulates erythropoiesis and causes an increase in sTfr and a decrease in ferritin.⁷⁴ Individuals with other causes of polycythemia or accelerated erythropoiesis also can exhibit increased ratios and be falsely accused of EPO use. An increased hematocrit with sTfr greater than 10 µg/mL and sTfr-to-serum protein ratio greater than 153 has been proposed as an indirect measurement of EPO use.¹²

At the 2000 Olympics in Sydney, Australia, a combination of multiple indirect markers was developed for detection of altered erythropoiesis and rhEPO use.¹⁵⁶ Current EPO use, known as the "ON-model," and recent, but not current, use of EPO, known as the "OFF-model," were identified by measured laboratory values. For example, five variables predict current rhEPO use: reticulocyte count, serum EPO concentration, sTfr, hematocrit, and percentage of macrocytes. The three variables in combination, including hematocrit, reticulocyte count, and serum EPO concentration, were the best mechanism for detecting recent rhEPO use.¹⁵⁶ A major drawback to this method is the instability of these variables in whole blood, so that confirmatory testing of the split blood sample is impossible.¹⁵⁷

State-of-the-art detection of EPO doping is accomplished by two techniques: isoelectric focusing and immunoblotting performed on urine samples. The two isoforms of EPO, recombinant and endogenous, have different glycosylation patterns and glycan sizes, resulting in differing molecular charges.¹⁵⁷ An immunoblotting procedure takes advantage of these different net charges, and the proteins can be separated by their charges when they are placed in an electric field.¹²³ Subsequently, by isoelectric focusing, this method obtains an image of EPO patterns in the urine.¹²² WADA considers a positive urine test result by this method definitive, even without the blood testing of indirect markers.¹⁵⁷ Because of the structural similarity of darbepoetin to EPO, these detection techniques also are effective for darbepoetin.¹⁵⁷

Athlete's Biological Passport. A significant development in the detection of blood transfusion, known as blood doping, is the development of a longitudinal record of an athlete's red blood cell (RBC) parameters called the athlete's biological passport. The detection of plasticizer metabolites from blood storage and alteration of gene expression resulting from infusion of autologous blood are proposed adjuncts to detection of autologous blood transfusion.¹⁴⁸ The observation of physiological parameters over time has made it easier to detect use of performance enhancing agents.¹⁶

STIMULANTS

Caffeine

Caffeine is a central nervous system stimulant that causes a feeling of decreased fatigue and increases endurance performance^{58,158} (Chap. 66). These changes may occur through several different mechanisms, including increased calcium permeability in the sarcoplasmic reticulum and enhanced contractility of muscle, phosphodiesterase inhibition and subsequent increased cyclic nucleotides, adenosine blockade leading to blood vessel dilation, and inhibited lipolysis. Caffeine is no longer prohibited by World Anti-Doping Code 2005 Prohibited List. Caffeine and pseudoephedrine are included in a monitoring program that was implemented by the WADA to detect patterns of misuse for substances that are no longer on the Prohibited List.²¹⁵

Amphetamines

The beneficial effects of amphetamines in sports result from their ability to mask fatigue and pain.⁴⁶ Initial studies done in soldiers showed that they could march longer and ignore pain when taking amphetamines (Chap. 76).²¹⁴ In one study in college students, resting and maximal heart rate, strength, acceleration, and anaerobic capacity increased. However, although the perception of fatigue decreased, lactic acid continued to accumulate and maximal oxygen consumption was unchanged.³⁷ Other studies have shown no significant effects on exercise performance¹⁰⁷.

Sodium Bicarbonate

Sodium bicarbonate loading, known as "soda loading," has a long history of use in horse racing.¹⁵ Sodium bicarbonate may buffer the metabolic acidosis associated with an elevated lactate caused by exercise, thereby delaying fatigue and enhancing performance.⁷⁶

During high-intensity exercise, metabolism becomes anaerobic and lactic acid is produced. Intracellular acidosis is said to contribute to muscle fatigue by reducing the sensitivity of the muscle contractile apparatus to calcium.¹⁶⁰ Several studies demonstrated improved performance in running when sodium bicarbonate was ingested 2 to 3 hours before competition.^{40,181} The study dose was 0.2 to 0.3 g/kg body weight of sodium bicarbonate, approximately 160 mEq of sodium bicarbonate per day. The effects of sodium bicarbonate are greatest when periods of exercise last longer than 4 minutes because anaerobic metabolism contributes more to total energy production and energy from aerobic metabolism diminishes.^{76,77} Adverse effects of bicarbonate loading include diarrhea, abdominal pain, and the possibility of hypernatremia.⁷⁶

An animal model demonstrated that intracellular acidosis associated with lactate production reversed muscle fatigue.^{4,160} Previously, intracellular acidosis was thought to contribute to muscle fatigue by reducing the sensitivity of the muscle contractile apparatus to calcium, decreasing the force of muscle contraction. However, the mechanism of excitation-contraction is complex. Because it permeates membranes easily, chloride is an important ion in maintaining and stabilizing the muscle fiber resting membrane potential at normal pH. Because of this, a large sodium current is needed to overcome membrane stabilization and produce an action potential. In the case of intracellular acidosis, the permeability of the membrane to the chloride ion is reduced, the resting membrane potential is no longer stabilized, and less inward sodium influx is needed to produce an action potential. The excitability of the muscle T-tubule system is therefore increased by acidosis, protecting against muscle fatigue.¹⁶⁰

DIURETICS

The WADA bans nonmedical diuretic use.²²⁹ Diuretics are used in sports in which the athlete must achieve a certain weight to compete in discrete weight classes. In addition to weight loss, body builders find that diuretic use gives greater definition to the physique as the skin draws tightly around the muscles.² In one report, a professional body builder attempted to lose weight using diuretics including bumetanide and spironolactone as well as potassium supplements. He presented with hyperkalemia and hypotension² (Chap. 19). Diuretics also result in increased urine production, thereby diluting the urine and making the detection of other banned xenobiotics more difficult.^{32,47}

LABORATORY DETECTION

Enormous amounts of energy and money are expended to determine the presence or absence of performance-enhancing xenobiotics. Analysis of samples on the international level is performed by a limited number of accredited laboratories. The majority of tests are performed on urine, with careful procedural requirements regarding handling of samples. Attention must be paid to proper storage of specimens, because bacterial metabolism may increase urinary steroid concentrations.^{24,51} Upon arrival of a sample at the testing laboratory, the integrity of the sample is checked, including the code, seal, visual appearance, density, and pH. Registration of the sample is completed, and the sample is divided into two aliquots. All testing is done on the first aliquot, and any positive results are confirmed on the second aliquot. The aliquots are commonly referred to as sample A and sample B. Sample preparation is difficult and time consuming.

The complexity of the laboratory testing and continuous attempts to evade detection is illustrated in the discovery of an AAS previously undetectable by standard sport doping tests of urine. In the following situation, there was no preexisting reference data for the unknown xenobiotic. In the summer of 2003, a used syringe was provided anonymously to the US anti-doping authority. Through a painstaking process of analyses, a previously unrecognized chemical in the syringe was identified as a derivative of the AAS norbolethone, a known reference compound, leading to the discovery, synthesis, and detection of tetrahydrogestrinone (THG), a new chemical unknown as a pharmaceutical or veterinary compound.³⁴ Since the discovery of THG, the identity of another designer steroid, madol, or desoxymethyltestosterone, was similarly discovered and the structure synthesized.¹⁹⁴

Capillary Gas Chromatography–Mass Spectrometry

Capillary gas chromatography allows the determination of approximately 95% of all doping positive results. Gas chromatography typically is combined with mass spectrometry for detection of the majority of substances.¹⁵⁰ Analysis of the urine by gas chromatography–mass spectrophotometry (GCMS) is the current standard for detection of AASs.³² Such analysis relies on a large amount of previously derived reference data.³⁴

Testosterone-to-Epitestosterone Ratio

GCMS cannot distinguish endogenous testosterone from pharmaceutically derived exogenous testosterone. Therefore, other methods of detection are needed. One way of detecting the use of exogenous testosterone is to measure the testosterone-to-epitestosterone (T/E) ratio. Epitestosterone is not a metabolite of testosterone, but its a 17- α epimer, differing from testosterone only in the configuration of the hydroxyl group on C-17. Men produce 30 times more testosterone than epitestosterone; however, 1% of testosterone and 30% of epitestosterone is excreted unchanged in the urine. Therefore, the normal T/E ratio in the urine is about 1:1.²⁰³ A T/E ratio less than 4:1 is considered acceptable; a T/E ratio greater than 4:1 is considered evidence of doping using testosterone. In order to maintain a normal T/E ratio, an athlete may self-administer both testosterone and epitestosterone.³³

The overall pattern of the T/E ratio over time is important. Athletes subjected to testing will have previous measurements of their T/E ratios on record with antidoping authorities, or additional tests may be obtained to establish a pattern of T/E ratios. These results are plotted against time. The mean, standard deviation, and confidence values are calculated.³³ The confidence values of three or more samples taken over months will be less than 60% unless the athlete is using testosterone.³⁴ Sudden variations in an athlete's pattern of T/E ratios over time is a cause for further testing.

In one high-profile doping case where the T/E ratio was elevated, the athlete suggested that ethanol consumption the previous night caused the elevated T/E ratio. In this regard, there is evidence that at very high doses, for example, 2 g/kg, ethanol increases the T/E ratio, although the T/E ratio did not exceed 6:1.⁶² This effect of ethanol is more pronounced in women and is limited to 8 hours postingestion of ethanol. The mechanism of this effect of ethanol may be that it increases the NADH-to-NAD⁺ ratio and many steroid oxidation-reduction reactions are dependent on the relative abundance of NADH to NAD⁺.⁶² Ketoconazole inhibits testosterone synthesis and may cause a decrease in the T/E ratio within 6 hours of administration.¹¹²

Isotope Ratio Mass Spectrometry

Carbon is made up of six protons and six neutrons, giving it an atomic weight of 12 (^{12}C). Sometimes carbon has an extra neutron, giving it an atomic weight of 13 (^{13}C). Carbon is derived from carbon dioxide in the atmosphere. Warm climate plants, such as soy, process carbon dioxide differently than other plants, using different photosynthetic pathways for carbon dioxide fixation, causing the depletion of ^{13}C .¹⁸⁶ Pharmaceutical testosterone is made from plant sterols, primarily soy plants, and therefore has less ^{13}C isotope than endogenous testosterone, made in the body from a typical human diet based in corn and not soy. This difference in isotope ratios is measured by isotope ratio mass spectrometry. An athlete's natural carbon makeup is determined by analysis of an endogenous reference compound such as the testosterone precursor cholesterol. Cholesterol may be called an "autostandard" because it represents the athlete's $^{13}\text{C}/^{12}\text{C}$ ratio.²⁰ Finally, it is the difference between the ratio of the athlete's $^{13}\text{C}/^{12}\text{C}$ ratio and an international standard ratio that is measured and reported.¹ Values are negative because both endogenous and pharmaceutical testosterone contain less ^{13}C than the international standard.⁸⁵

Insulin

Laboratory detection methods for insulin are not yet standardized and accredited by WADA. Therefore, athletes are not currently tested for insulin use. The technology for testing for insulin uses immunoaffinity purification followed by liquid chromatography–tandem mass spectrometry to identify analytes including urinary metabolites of insulin.²¹² When insulin is modified to improve its receptor selectivity or give it other favorable properties, the change in molecular weight or amino acid profile from human insulin makes it detectable by GCMS.²¹²

Masking Xenobiotics

Any chemical or physical manipulation done with the purpose of altering the integrity of a urine or blood sample is prohibited by WADA.²²⁹ For example, use of intravenous fluids for dilution of the sample, or urine substitution, is prohibited. Some xenobiotics are added to the urine for the sole purpose of interfering with urine testing and are easily detected. Examples include "Klear," which is 90% methanol, and Golden Seal tea, which produces colored urine.²⁸ Other commercially available products include "Xxtra Clean," which contains pyridinium chlorochromate, and "Urine Luck," which contains glutaraldehyde.

Niacin has been used to alter urine test results, although there is no evidence it is effective for this purpose. There are reports of niacin toxicity, including skin reactions such as itching, flushing, and burning when niacin is used for this purpose.^{35,144} More serious symptoms, including nausea, elevated liver enzymes, hypoglycemia, and anion gap metabolic acidosis, are reported as a result of ingesting niacin in large amounts, in the 2.5 to 5.5 g range over 1 to 2 days.^{35,144}

A significant issue in the analysis of urine for the presence of prohibited peptides such as rEPO is the masking potential of proteases surreptitiously added to urine specimens slated for doping analysis. The proteases are packaged in "grains" known as protease granules or "rice grains" and placed in the urethra.²⁰⁹ Upon urination for the purpose of providing a specimen for doping analysis, the grain flows with urine into the specimen cup. The proteases, including trypsin, chymotrypsin, and papain, will quickly degrade renally excreted peptides, most notably EPO, making them undetectable. By the process of autolysis, proteases may themselves become undetectable over time. In one report, urine with elevated protease concentrations greater than 15 $\mu\text{g}/\text{mL}$ underwent further analysis to identify urinary proteins such as albumin.²⁰⁹ Normally, the presence of urinary proteins creates the image of a visible band by gel electrophoresis. However, the urine with elevated protease activity may demonstrate something called trace of burning, a term indicating an absence of proteins.²¹⁰ In this report, suspicious specimens were subjected to further testing using liquid chromatography–mass spectrometry. After further molecular sequencing of derived proteins, human proteases can be distinguished from nonhuman proteases, such as bovine chymotrypsin or papain. The addition of a protease inhibitor to urine samples immediately after collection may be a future strategy to control the effectiveness of protease addition as a masking method.²¹⁰

In approximately 15% of urine samples performed in anti-doping laboratories, there is no endogenous or rEPO detectable by immunoelectrophoresis.¹¹⁹ Undetectable EPO occurs more commonly in competition, the "competition effect." This is due in part to circumstances that may be unrelated to doping, such as physiological variation in EPO production, gender, and very low or very high urine specific gravity. However, doping with exogenous rEPO and inhibition of endogenous hEPO production or addition of proteases are other possible causes. Strenuous effort causes a shift in the isoforms of EPO yielding a more basic isoelectric point, a result known as "effort" urine.¹¹⁸ In any case, a urine deemed as suspicious may ultimately not result in a positive doping test result.^{119,209}

The list of prohibited masking xenobiotics includes diuretics, epitestosterone, probenecid, plasma expanders such as albumin, dextran, and hydroxymethyl starch, and α -reductase inhibitors such as finasteride and dutasteride.²²⁹ Probenecid blocks urinary excretion of the glucuronide conjugates of AAS.

Gene Doping

The discovery of the genetic codes for some diseases has made gene therapy of medical conditions, such as muscular dystrophy, a reality. It is now conceivable that this technology can be used to enhance athletic performance. Gene doping is included on the WADA 2013 Prohibited List.²³⁰ Gene doping is defined as “the non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athlete performance.”²²⁹ For example, insertion of a gene sequence could produce a desired effect, such as large muscles or increased body production of potentially advantageous substances such as testosterone or growth hormone. In animal models, genes for EPO lead to erythropoiesis and genes for IGF-1 produce increased muscle size and strength.¹⁸ Myostatin, which belongs to a family of proteins that control growth and differentiation of tissues in the body, inhibits skeletal muscle growth.^{102,190} Mutations of the myostatin gene may result in muscle hypertrophy. In dogs, the athletic performance of racing whippets is enhanced in those animals with a myostatin gene mutation.¹⁴⁹ In humans, a report of an extremely muscular baby born with a mutation in the myostatin gene illustrates the potential effect of gene alterations on athletic performance. The mother of this infant was a professional athlete, and other members of the family were known for their strength.¹⁹⁰ Transcription regulators such as AMP-activated protein kinase (AMPK) are exercise mimetics and increase muscle endurance when administered orally in animal models.^{81,151} Influencing the expression of the transcription factor peroxisome proliferator-activated receptor- δ (PPAR- δ), a nuclear hormone receptor hormone protein, leads to increased formation of slow twitch skeletal muscle. Angiotensin II receptor blockers such as telmisartan influence both the AMPK pathway and up-regulate PPAR- δ expression improving muscle performance.⁶³

PERFORMANCE ENHANCEMENT AND SUDDEN DEATH IN ATHLETES

Many unexpected deaths in certain groups of young competitors have occurred in the absence of obvious medical or traumatic causes. In some of these cases, the use of performance-enhancing drugs was linked to the deaths. The use of EPO, introduced in Europe in 1987, may have contributed to the large number of deaths in young European endurance athletes over the next several years.^{57,78,138,161,223} In young healthy athletes experiencing cerebrovascular events or myocardial infarction, the temporal link between the use of cocaine, ephedrine, or performance enhancers such as AASs suggests a role for these xenobiotics as precipitants of these adverse events.¹³⁵ Nevertheless, the leading cause of nontraumatic sudden death in young athletes is most often associated with cardiac anomalies.¹³³ In autopsy studies of athletes in the United States with sudden death, hypertrophic cardiomyopathy is the most common structural abnormality, accounting for more than one-third of the cardiac arrests, followed by coronary artery anomalies.¹³⁵ In Italy, dysrhythmic right ventricular cardiomyopathy is implicated in one fourth of these deaths.^{66,106,136,218} Medical causes of sudden death other than cardiac causes include heat stroke ([Chap. 30](#)), sickle cell trait, and asthma.

SUMMARY

- Although the press spotlights a few world-class athletes, the vast majority of individuals using performance-enhancing substances are not in the public view. Some individuals suffer adverse consequences. The knowledgeable clinician will identify these health effects when they occur and educate susceptible individuals on the health risks of using performance enhancing substances.
- Continuous development and refinement of anti-doping laboratory methods broadly benefits our understanding of the physiology of exercise.
- WADA is the international body responsible for coordinating anti-doping efforts nationally and internationally, and as such the WADA Prohibited List sets the standard for methods and substances barred in sport.

41 BOTULISM

Howard L. Geyer

HISTORY AND EPIDEMIOLOGY

Botulism, a potentially fatal neuromuscular illness, results from exposure to botulinum neurotoxin (BoNT), which is produced by the bacterium *Clostridium botulinum* and other *Clostridium* species. The earliest cases of botulism were described in Europe in 1735 and were attributed to improperly preserved German sausage; the name of the disease alludes to this association, *botulus* being Latin for sausage. Emile van Ermengem identified the causative organism in 1897 and named it *Bacillus botulinum*; it was later renamed *Clostridium botulinum*.²² These Gram-positive, spore-forming bacteria produce seven serotypes of BoNT, denoted A through G.

In adults, most cases are due to contaminated food, resulting from ingestion of toxin, whereas in infants most cases result from ingestion of bacterial spores which proliferate and produce toxin in the gastrointestinal (GI) tract. Less common forms of botulism include wound botulism, in which spores are inoculated into a wound and locally produce toxin, and inhalational botulism due to aerosolized BoNT, potentially used as a weapon of bioterrorism.

Botulism outbreaks can occur anywhere in the world¹¹⁵ and have been reported from such diverse areas as Iran,¹⁰³ Japan,⁹⁷ Thailand,⁷⁰ France,¹ Portugal,⁷⁴ and Canada.⁹¹ In 2011, a total of 140 cases of botulism were reported to the US Centers for Disease Control and Prevention (CDC). Food-borne botulism constituted 14% of cases, infant botulism 73% of cases, and wound botulism 9%.³⁸ In this analysis, toxin type A accounted for the majority of cases of food-borne botulism (70%) and all cases of wound botulism, and infant botulism was due to toxin type A in 40% and to toxin type B in 59% of cases.³⁸ No deaths from food-borne botulism were reported in 2011. The case fatality rate has improved for all botulism toxin types, probably due to increasing awareness of the condition and consequent earlier diagnosis, appropriate and early use of antitoxin, and better and more accessible life support techniques.

In the past 50 years, home-processed food has accounted for 65% of outbreaks, with commercial food processing constituting only 7% of reported cases; in the remaining outbreaks, the origin is unknown.³⁴ Common home-canning errors responsible for botulism include failure to use a pressure cooker and allowing food to putrefy at room temperature. Minimally processed foods such as soft cheeses may lack sufficient quantities of intrinsic barriers to BoNT production, such as salt and acidifying agents.¹⁰⁹ These foods become high-risk sources of botulism when refrigeration standards are violated. The US Food and Drug Administration (FDA) continuously reviews recommendations for appropriate measures to process such foods.^{137,138}

Awareness of evolving trends and unusual presentations or locations of botulism permits the establishment of preventive education programs. Outbreaks of botulism have been associated with specialty foods consumed by different ethnic groups, such as chopped garlic in soy oil by Chinese in Vancouver, British Columbia^{91,132}; uneviscerated salted fish—called *kapchunka*—eaten by Russian immigrants in New York City^{37,136}; and the same fish—called *faseikh*—eaten in Egypt.¹⁴⁷ The incidence of botulism is high in Alaska where traditional foods include fermented fish and fish eggs, seal, beaver, and whale; between 1990 and 2000, 39% of cases of food-borne botulism in the United States occurred in Alaska.¹²⁹ Approximately 90% of toxin type E outbreaks have occurred in Alaska because of home-processed fish or meat from marine animals,^{39,76,146} while one incident occurred in New Jersey.⁴⁰ In the 1990s, three cases of botulism involved members of a Native American church after they ingested a ceremonial tea made from the buttons of dried, alkaline-ground peyote cactus that were prepared in a water-covered refrigerated jar. The resultant alkaline and anaerobic milieu presumably fostered the growth of toxin from naturally occurring spores.⁶³ In 1996, eight cases of food-borne botulism in Italy were linked to mascarpone cream cheese eaten either alone or in tiramisu contaminated with BoNT type A.¹⁴ In 2006, carrot juice was implicated in four cases in Georgia and Florida.³¹ Ten cases in California, Indiana, Ohio, and Texas were linked to commercially processed chili sauce in 2007.³¹ In October 2011, eight maximum security inmates at the Utah State Prison developed botulism from drinking “pruno,” an illicit alcoholic brew. A baked potato saved from a meal served weeks earlier was added to the “pruno” and was suspected as the source of *C. botulinum* spores.³³

Among cases attributed to commercial food processing, vegetables (peppers, beans, mushrooms, tomatoes, and beets, with or without meat) were thought to be the causative agents in approximately 70%, meat in 17%, and fish in 13% of cases.³⁴ Although only 4% of food-borne botulism is associated with food purchased in restaurants, restaurant-related

outbreaks usually affect large numbers of individuals.⁷⁶

Of 20 reported cases of food-borne intoxication in 2011, there were two multi-case outbreaks, involving three and eight cases, respectively.³⁸ Among hundreds of outbreaks from 1975 to 1988 totaling more than 400 persons, approximately 70% involved only one person, 20% involved two persons, and only 10% involved more than two persons, yielding a mean of 2.7 cases per outbreak.¹⁵¹ Single affected patients were more severely ill, with 85% requiring intubation compared to only 42% requiring intubation in multi-person outbreaks,¹⁵¹ presumably because diagnosis in the index case leads to more rapid therapeutic intervention for associated cases.

Infant botulism is more common in certain geographic areas, presumably due to higher concentrations of botulinum spores in soil. Raw honey is a potential source of spores.⁹² Most affected infants are younger than 6 months of age. Of 102 cases reported in 2011, most were from California (28%), Pennsylvania (13%), and New Jersey (11%). The median age was 17 weeks, and 77% were male. No US deaths from infant botulism were reported in 2011.³⁸ With appropriate support and treatment, a favorable outcome is achieved in the majority of cases.

In 2011, 13 cases of wound botulism were reported; 9 of those cases occurred in California. Ages ranged from 5 to 62 years, with a median of 38 years. One suffered a wound in a motorcycle crash and another sustained a facial wound that involved bark; all the others were injection drug users. No deaths from wound botulism were reported in the United States in 2011.³⁸

In recent years, concern about the use of inhalational BoNT as a biologic weapon has increased. In ways unimaginable when the first edition of this book was published, medical and public health realities associated with terrorism in the 21st century, unfortunately, have resulted in increased relevance of botulism to medical practitioners ([Chaps. 132 and 133](#)). The advent of therapeutic BoNT injections has raised other concerns regarding potential adverse consequences.¹¹

BACTERIOLOGY

The genus *Clostridium* comprises a group of four spore-forming anaerobic Gram-positive bacillary species that produce seven different neurotoxic proteins. *C. botulinum* produces all BoNT serotypes A through G, *Clostridium baratii* produces toxin type F, *Clostridium butyricum* produces toxin type E, and *Clostridium argentinense* produces toxin type G.^{64,121,126} Rare instances of both adult and infant botulism are attributed to *C. baratii* and *C. butyricum*.^{62,85,98,105} The reported incidence of cases due to BoNT type F may be underestimated because of the only recent capacity of most laboratories to determine the presence of *C. baratii* and other clostridial species producing toxin type F.⁶²

Clostridial species are ubiquitous, and the bacteria and spores are present in soil, seawater, and air.¹²⁸ Seven main toxin types, labeled A through G, are recognized, but genomic sequence analysis shows that multiple subtypes can exist within each category.⁶⁷ In the United States, toxin type A is found in soil west of the Mississippi⁷⁸; type B is found east of the Mississippi, particularly in the Allegheny range; and type E is found in the Pacific northwest and the Great Lakes states.^{35,128} Toxin types A and B typically are found in poorly processed meats and vegetables. Toxin type E is commonly found in raw or fermented marine fish and mammals. Toxin types C and D cause disease in birds and mammals. Toxin type G has not been associated with naturally occurring disease. Although the different botulinum toxins differ in the cellular molecules they target, their ultimate pathophysiology and clinical syndromes are identical.

All botulinum spores are dormant and highly resistant to damage. They can withstand boiling at 212°F (100°C) for hours, although they usually are destroyed by 30 minutes of moist heat at 248°F (120°C). Factors that promote germination of spores in food are pH greater than 4.5, sodium chloride content less than 3.5%, or a low nitrite concentration. Most viable organisms produce toxin in an anaerobic milieu with temperatures greater than 80.6°F (27°C), although some strains produce toxins even when conditions are not optimal. *C. botulinum* organisms can produce toxin type E at temperatures as low as 41°F (5°C). To prevent spore germination, acidifying agents such as phosphoric or citric acid are added to canned or bottled foods that have a low acid content, such as green beans, corn, beets, asparagus, chili peppers, mushrooms, spinach, figs, olives, and certain nonacidic tomatoes. Unlike the spores, the toxin itself is heat labile and can be destroyed by heating to 176°F (80°C) for 30 minutes or to 212°F (100°C) for 10 minutes. At high altitudes, where the boiling point of water may be as low as 202.5°F (94.7°C), boiling for a full 30 minutes is prudent in order to ensure that the toxin has been destroyed. Under high-altitude conditions, pressure cooking at 13 to 14 lb of pressure often is necessary to achieve appropriate temperatures to destroy the toxin in a timely fashion.

Food contaminated with *C. botulinum* toxin types A and B may look or smell putrefied because of the action of proteolytic enzymes.⁶¹ In contrast, because toxin type E organisms are saccharolytic and not proteolytic, food contaminated with toxin type E may look and taste normal.¹⁶

PHARMACOKINETICS AND TOXICOKINETICS

BoNT is the most potent toxin known. The LD₅₀ for mice is 3 million molecules injected intraperitoneally. The human oral

lethal dose is 1 µg/kg.¹¹⁴

Food-borne botulism results from ingestion of preformed BoNT from food contaminated with *Clostridium* spores. The toxin is complexed to associated proteins (hemagglutinins and a nontoxic nonhemagglutinin),¹²⁶ which protect it from the acidic and proteolytic environment in the stomach. In the intestine, the alkaline pH dissociates the toxin from the associated proteins, allowing for subsequent absorption into the bloodstream.⁸⁹ Because the toxin is often demonstrated only in the stool, determining the percentage of the toxin actually absorbed is difficult.^{49,51} The median incubation period for all patients is 1 day, but ranges from 0 to 7 days for toxin type A, 0 to 5 days for toxin type B, and 0 to 2 days for toxin type E.¹⁵¹

Infant botulism results not from ingestion of preformed BoNT but from ingestion of *C. botulinum* spores, which germinate in the GI tract and produce toxin. The immaturity of the bacterial flora in the infant GI tract facilitates colonization by the *Clostridia*. Adults with altered GI tracts (such as those who have undergone gastric bypass or are taking proton pump inhibitors or H₂ antagonists) can also develop botulism in the same way, with the onset of symptoms typically following ingestion by a month or two. A single case of food-borne botulism in a 6 month-old infant associated with home-canned baby food is reported.⁶

In wound botulism, spores proliferate in a wound or abscess and locally elaborate toxin. The incubation period is typically less than 2 weeks, but delays as long as 51 days are reported.⁶⁶

The duration of action of the BoNT types may vary, depending on the components of the neurotransmitter release apparatus that are disrupted (see Pathophysiology). The persistence of clinical effect may result from the individual cleavage target, the intraneuronal biological half-life of the toxin, or both. Current evidence indicating intraneuronal toxin metabolism or elimination is inadequate.¹²⁵

PATHOPHYSIOLOGY

BoNT is produced as a protein consisting of a single polypeptide chain with a molecular weight of 900 kDa, which includes a 750 kDa nontoxic protein and a 150 kDa neurotoxic component. To become fully active, the single-chain polypeptide 150 kDa neurotoxin must undergo proteolytic cleavage to generate a dichain structure consisting of a 100 kDa heavy chain linked by a disulfide bond to a 50 kDa light chain. The dichain form of the molecule is responsible for all clinical manifestations.^{26,64} Both the single polypeptide chain toxin and the dichain form are resistant to GI degradation.⁸⁰

The ingested toxin binds to serotype specific receptors on the mucosal surfaces of gastric and small intestinal epithelial cells, where endocytosis is followed by transcytosis, which permits release of the toxin on the serosal (basolateral) cell surface.^{72,79} The dichain form travels intravascularly to peripheral cholinergic nerve terminals, where it binds rapidly and irreversibly to the cell membrane and is taken up by endocytosis. The heavy chain is responsible for cell specific membrane binding to acetylcholine containing neurons (Fig. 41–1).¹⁰¹

FIGURE 41–1. Botulinum toxins consist of two peptides linked by disulfide bonds. The heavy chain is responsible for specific binding to acetylcholine (ACh) containing neurons. Following binding to the cell surface, the entire complex undergoes endocytosis and subsequent translocation of the light chain into the nerve cell cytoplasm. The light chain contains a zinc-requiring endopeptidase that cleaves soluble N-ethylmaleimide sensitive factor (NSF) attachment protein receptor (SNARE) proteins belonging to the docking/fusion complex required for neuroexocytosis of ACh. These proteins may be associated with the synaptic vesicles (v-SNARE) or with their targets on the presynaptic membrane (t-SNARE). Botulinum toxin types A and E proteolyse the t-SNARE protein known as synaptosomal-associated protein (SNAP)-25, and BoNT type E cleaves both SNAP-25 and syntaxin, which is attached to SNAP-25 and to the presynaptic membrane. BoNT types B, D, F, and G target the v-SNARE protein synaptobrevin. As a result of cleavage of these components of the docking complex by the endopeptidase, ACh is not released and neuromuscular transmission is impaired.

Once inside the cell, the light chain acts as a zinc-dependent endopeptidase to cleave presynaptic membrane polypeptides that are essential components of the soluble N-ethylmaleimide-sensitive factor attachment receptor (SNARE) apparatus which subserves acetylcholine exocytosis, thereby inhibiting release.¹¹⁴ BoNT types specifically cleave different proteins belonging to the SNARE family, and these differences may be responsible for their variable toxicity.¹²³ SNARE proteins targeted by proteolysis include vesicle associated membrane protein (VAMP, also known as synaptobrevin) localized on synaptic vesicles, syntaxin found on the presynaptic membrane, and synaptosomal associated protein (SNAP)-25, which is attached to syntaxin and to the presynaptic membrane. Toxin types A and E cleave SNAP-25; types B, D, F, and G act on VAMP/synaptobrevin; and type C cleaves both syntaxin and SNAP-25 (Fig. 41–1).⁷² All BoNT types impair transmission at acetylcholine-dependent synapses in the peripheral nervous system, but cholinergic synapses in the central nervous system are not thought to be affected. Very high concentrations of BoNT can also impair release of other neurotransmitters including norepinephrine and serotonin.⁶⁰

CLINICAL MANIFESTATIONS

Food-Borne Botulism

Although botulism is the most dreaded of all food poisonings, the initial phase of the disease often is so subtle that it goes unnoticed. Botulism often is misdiagnosed on the first visit to a health care provider.^{27,152} When GI effects are striking and food poisoning is suspected, the differential diagnosis should include other acute poisonings, such as metals, plants, mushrooms, and the common bacterial, viral, and parasitic agents discussed in Chap. 44.

Onset of symptoms typically occurs the day following ingestion. Early GI signs and symptoms of botulism include nausea, vomiting, abdominal distension, and pain. A time lag (from 12 hours to several days, but typically not more than 24 hours) may be observed before neurologic signs and symptoms appear. Common findings include diplopia (often with lateral rectus palsy), blurred vision with impaired accommodation, and bilaterally symmetric flaccid paralysis that typically begins in cranial muscles and descends to the limbs. Constipation due to smooth muscle involvement is frequent, and urinary retention and ileus may also occur. Dry mouth, dysphagia, and dysarthria/dysphonia (manifested by a nasal quality to the voice) may be severe, and many patients exhibit fixed mydriatic pupils with ptosis. Deep tendon reflexes are usually reduced or absent. Hypotension and bradycardia sometimes develop, but temperature regulation is normal.

Weakness of respiratory muscles may necessitate intubation and mechanical ventilation. Approximately 67% of patients with toxin type A require intubation, compared to 52% of patients with toxin type B, and 39% with toxin type E botulism.¹⁵¹

Importantly, mental status and sensation remain normal. These negatives, along with the absence of tachycardia, distinguish botulism from the anticholinergic syndrome, which shares many features with botulism.

The differential diagnosis of botulism includes a variety of toxicologic and nontoxicologic conditions (Tables 41–1A and 41–1B). All of these disorders have weakness as a prominent feature, but many can be differentiated readily from botulism based on their more chronic time course. The most difficult and frequently encountered diagnostic challenge is differentiating between botulism and the Miller Fisher variant of the Guillain-Barré syndrome (Table 41–2). Because physicians so rarely encounter botulism (especially compared to other much more common disorders in the differential diagnosis), initiation of appropriate management often is seriously delayed. The index case of an epidemic or an isolated case often is misdiagnosed at a stage when the risk of morbidity and mortality still could be substantially diminished. This is particularly true of toxin type E botulism, which typically initially causes much more prominent GI signs than neurologic signs.¹⁶ The differences in the initial clinical symptoms associated with the various serotypes may be related to the presence of proteolytic enzymes in toxin types A and B and saccharolytic enzymes in toxin types E and C botulism.

TABLE 41–1A. Toxicologic Differential Diagnosis of Botulism

<i>Condition</i>	<i>Associated Findings</i>
Aminoglycosides	Postanesthetic paralysis
Anticholinergics	Mydriasis, vasodilation, fever, tachycardia, ileus, dry mucosa, urinary retention, altered mental status
Buckthorn (<i>Karwinskia humboldtiana</i>)	Rapidly progressive ascending paralytic neuropathy with quadriplegia
Carbon monoxide	Headache, nausea, altered mental status, tachypnea, elevated carboxyhemoglobin level
Diphtheria (demyelinating neuropathy)	Exudative pharyngitis, cranial polyneuropathy (late), cardiac manifestations, hypotension
Elapid (coral snake) envenomation	Euphoria, lightheadedness, fasciculations, tremor, weakness, salivation, nausea, vomiting followed by bulbar palsy and paralysis including slurred speech, diplopia, ptosis, dysphagia, dyspnea, respiratory compromise
Organic phosphorus pesticides	Salivation, lacrimation, urination, defecation, miosis, fasciculations, bronchorrhea, delayed neuropathy
Paralytic shellfish poisoning	Incubation <1 hour, dysesthesias, paresthesias, altered mental status, respiratory paralysis
Thallium	Alopecia, painful ascending sensory neuropathy, constipation, cranial neuropathy, Mees lines

TABLE 41–1B. Nontoxicologic Differential Diagnosis of Botulism

<i>Condition</i>	<i>Associated Findings</i>
Lambert-Eaton myasthenic syndrome	Neoplasm (especially small cell lung cancer), limb weakness exceeding ocular/bulbar weakness, increased strength following sustained contractions, postexercise facilitation on repetitive nerve stimulation, antibodies to voltage-gated calcium channels
Encephalitis	Fever, altered mental status, seizures, CSF showing elevated protein and pleocytosis
Food "poisoning" (other bacterial)	Rapid onset of disease, absence of cranial nerve findings
Guillain-Barré syndrome/acute inflammatory demyelinating polyneuropathy (and Miller Fisher variant)	Areflexia, paresthesias, ataxia, CSF showing elevated protein without pleocytosis, slowed nerve conduction velocity
Hypermagnesemia	Respiratory compromise, diffuse flushing, weakness, thirst
Inflammatory myelopathies	Complete (transverse) or incomplete spinal syndrome with paraparesis and/or sensory level, back pain, may be preceded by viral illness, CSF pleocytosis
Myasthenia gravis	Aggravation of fatigue with exercise, fluctuating weakness, positive edrophonium (Tensilon) test, acetylcholine receptor antibodies, decremental response on rapid repetitive nerve stimulation
Poliomyelitis	Fever, gastrointestinal symptoms, asymmetric neurologic findings; CSF showing elevated protein and pleocytosis
Polymyositis	Insidious onset, proximal limb weakness, dysphagia, muscle tenderness sometimes present, elevated creatine kinase, aldolase, c-reactive protein and erythrocyte sedimentation rate, fibrillations and sharp waves on electromyography
Stroke	Asymmetric paralysis, abnormal brain imaging
Tetanus	Rigidity, cranial nerves usually normal
Tick paralysis (<i>Dermacentor</i> species)	Rapidly evolving paralysis, ptosis, absence of paresthesias, normal CSF analysis, presence of an embedded tick with resolution upon removal
